Mice were primed i.p. with 200 μ g of dinitrophenyl (DNP)-KLH (312 DNP groups per 10^6 molecular weight) and 10^9 *Bordetella pertussis* organisms. The mice were boosted with 20 μ g DNP-KLH i.p. 7 d before killing. Spleen cells were cultured directly with DNP-KLH or after treatment with mouse anti-Thy 1 and complement¹⁶. T-helper cells were obtained from C57B1/6 mice primed with KLH and boosted 3 d before use. In reconstitution experiments, 1×10^6 Thy 1 + C'-treated cells were cultured with 4×10^6 helper cells in 0.5 ml of medium. Treatment of helper cells with anti-FLV GP71: 3×10^7 cells, 30 min on ice with 0.5 ml of 1:5 diluted serum. After washing, cells were incubated with 0.5 ml of 1:5 diluted rabbit complement and washed twice.

received DNP-KLH, another SRBC. The secondary immune response to DNP-KLH *in vitro* was practically abrogated by the antiserum treatment (Fig. 1). Although the anti-SRBC response was also reduced, it still was about 100-times higher on a percentage of control basis than the anti-DNP response. This suggests a remarkable specificity of the treatment which indeed seems to predominantly effect antigen-activated lymphocytes (DNP-specific) while unstimulated cell clones (SRBC-specific) are preserved. In principle, an antigen-specific immune suppression seems to be possible in these experimental conditions by applying appropriate antisera against oncoviral antigens such as GP71. Also, using type-specific antisera, it will now be possible to characterise the type of endogenous viruses, the antigens of which

Fig. 1 Specificity of anti-GP71 antisera for antigen-activated lymphocytes. DBA/2 mice were used. The condition of *in vitro* priming and boosting, and antiserum treatment before culture were as described in Table 2. One set of cultures received KLH-activated helper cells and DNP-KLH as antigen, the other received SRBC and TRF on day 2 for reconstitution of T-helper function¹⁷. Samples a-d all underwent T-cell reduction. a, NGS + C' + helper; b, anti-GP71 + C' + helper; c, NGS + C' + helper; d, anti-GP71 + C' + helper. The value for b is 0.3%.

Table 1 Effect of anti-GP71 antiserum and complement on anti-SRBC response *in vitro*

Additions on day 3	PFC per 10^6 cells, day 5 (anti-SRBC IgM)	% Control
None (control)	1,377	100
NGS + complement	1,033	75
Anti GP71 + complement	197	14
Anti GP71 + inactivated complement	1,522	110
Inactivated anti GP71	1,640	119
Inactivated anti GP71 + complement	88	6

5×10^6 spleen cells of $B_6D_2F_1$ mice in 0.5 ml of medium containing 5% FCS were cultured together with 2.5×10^6 SRBC¹¹. On day 3, cultures received 0.1 ml of the respective sera diluted 1:5 and 0.05 ml of undiluted rabbit complement or 0.05 ml of medium. 1.5 ml of the diluted sera had been absorbed for 3 h on ice with suspended cells equivalent to one liver and one spleen of $B_6D_2F_1$ mice. Heat inactivation was performed 30 min incubation at 60 °C.

can be expressed on lymphocyte surfaces of the various mouse strains.

These findings are compatible with the notion that the expression of endogenous viral antigens may generally have a role in cellular proliferation and/or differentiation. Using cells of the immune system might prove quite helpful in studying these questions. All immune reactions are characterised by proliferation and differentiation of the responding lymphocytes. Both events can be induced consecutively and *in vitro* by distinct signals¹⁷. The appearance of endogenous viral antigens in dependence of one or both events can thus be studied in detail.

We thank Dr Werner Schäfer (Max-Planck-Institute for Virus Research, Tübingen) for a gift of antisera and for useful discussions, and Ms R. Weck and Mr A. Zant for technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft.

Are endogenous C-type viruses involved in the immune system?

DNA sequences coding for infectious C-type viruses (oncornaviruses) are present in the genome of normal cells of various species, those best characterised being chicken, mouse, cat and baboon¹. Mammalian endogenous viruses, in general, are restricted for growth in their autologous species but replicate in autologous species and are termed xenotropic². In mice and some other species a further class of endogenous viruses has evolved which is restricted in heterologous cells but replicates in homologous cells, they are termed ecotropic³. Endogenous viral genes are inherited in the germ line and have co-evolved, in general, with non-viral host genes as indicated by evolutionary data⁴. One explanation for the retention of these genes is that they are involved in physiological functions as proposed by Temin in his provirus hypothesis⁵. We have shown previously that B-cell proliferation induced by certain B-cell mitogens is frequently associated with expression of endogenous virus^{6–10}. This has been confirmed by other workers who reported a xenotropic host range of the mitogen-induced virus¹¹. In contrast to other virus induction methods, mitogen stimulation closely resembles a physiological process, that of antigen stimulation followed by lymphocyte proliferation. Whereas B cells can be induced by mitogens to release virus, we have evidence that T cells are refractory to induction when using T-cell mitogens as well as 5-bromo-2'-deoxyuridine⁸. These results suggest that the expression of endogenous xenotropic C-type viral genes

may be physiologically required for B cells to participate in the immune response. As a test of this hypothesis we examined the effect of antisera directed against xenotropic endogenous C-type virus on the humoral immune response of mice. We show here that such sera are immunosuppressive.

To obtain an antiviral serum with no activity against non-viral mouse cellular components, we immunised rabbits with mouse xenotropic C-type virus produced in a rabbit cell line (SIRC). This rabbit line had been infected with endogenous C-type virus induced from BALB/c spleen cells by the B-cell mitogen lipopolysaccharide and was used as virus source 8 months after infection. For absorption controls, the same virus was purified from the culture fluid of a similarly infected mink cell line (CCL-64). The sera used in these studies were obtained from two rabbits following multiple intramuscular injections each of approximately 0.2 mg viral protein emulsified in complete Freund's adjuvant. Sera taken from the same animals before immunisation were used as controls. Sera was complement inactivated by heating at 56 °C for 30 min. The immune sera displayed complement-dependent cytotoxicity on virus-infected SIRC cells and showed no activity on uninfected SIRC cells. Pre-immune sera were not cytotoxic.

We examined the effect of antiviral sera on the humoral immune response to sheep red blood cells (SRBC) as assayed in the Mishell–Dutton *in vitro* system¹². In this assay B cells which secrete antibody against SRBC are quantitated by their plaque-forming ability. A typical experiment is presented in Table 1 which shows that antiserum but not control serum reduces the number of plaque-forming cells by 70%.

To confirm the viral specificity of the immunosuppressive effect of our antisera, absorption experiments were performed with equal quantities of various viruses as well as with SRBC. Table 2 shows that absorption of the antiserum with xenotropic virus fully removed the immunosuppressive activity. Xenotropic BALB/c virus, grown in mink or rabbit cells, as well as xenotropic AKR virus, were similarly effective in absorption. Some absorption occurred also with ecotropic AKR virus, while tobacco mosaic virus, a completely unrelated virus, showed no absorption. Since rabbit antisera frequently contain activity against Forssman antigen, we tested whether absorption with red cells would remove the immunosuppressive activity. As shown in Table

Table 1 *In vitro* immunosuppressive activity of antiserum against mitogen-induced xenotropic C-type virus

Serum (final dilution)	PFC per 10 ⁵ spleen cells*	% Inhibition
—	3,900	—
Control serum (1:100)	3,900	0
Antiserum (1:100)	1,200	70
(1:400)	1,900	51
(1:1,600)	1,700	56
(1:6,400)	3,800	3

The effect of the antiserum against xenotropic C-type virus on the induction of an antibody response to sheep red blood cells was investigated in cultures of BALB/c spleen cells from 8–15-week-old mice by a modified Mishell–Dutton technique¹². 8×10^6 spleen cells were cultured in 35×10 -mm disposable tissue culture Petri dishes (Falcon) containing 1 ml RPMI 1640 medium (Microbiological Associates), supplemented with 8% foetal bovine serum, 1% horse serum and antibiotics. At the onset of the culture period 10 μ l control serum or antiserum was added. The cultures were rocked during the 5-d culture period in an incubator containing 10% CO₂, 83% N₂ and 7% O₂. They were stimulated with 4×10^6 sheep red blood cells. Direct plaque-forming cells (PFC) were assayed by the local haemolysis technique in liquid medium¹³. The cell recovery of the various cultures did not differ significantly.

*Mean values from triplicate cultures.

	+	Rabbit RBC	600	90

The antiserum was absorbed with either virus or red blood cells. Virus absorption: 400 µg of density-gradient purified virus was pelleted by centrifugation and incubated with 30 µl of sera diluted 1:10 for 60 min in ice. Serum was recovered by centrifugation and 10 µl of the absorbed serum was added to 1 ml cultures. Absorption with red blood cells: 1 part packed cell volume was incubated with 2 parts of sera diluted 1:2 for 30 min on ice. Serum was recovered by centrifugation and subjected to two further absorption procedures. Finally, the serum was clarified by centrifugation in a Sorvall SS 34 rotor at 5,000 r.p.m. for 10 min. Cultures received 10 µl of the absorbed sera or 10 µl of the non-absorbed serum 1:10 diluted. Culture conditions as Table 1.

*Mitogen-induced endogenous xenotropic BALB/c virus, grown in mink CCL-64 cells.

†Mitogen-induced endogenous xenotropic AKR virus, grown in mink CCL-64 cells.

§Tobacco mosaic virus.

As *, but virus grown in rabbit SIRC cells.

2, this was not found to be the case. Furthermore, no absorption occurred when the serum was incubated with rabbit SIRC cells (data not shown).

The immunosuppression was also shown in experiments carried out *in vivo*. Four days after immunisation with SRBC those mice which had simultaneously received an intravenous injection of 0.2 ml antiviral serum showed a reduced number of plaque-forming cells, inhibition ranging from 75 to 84% (Table 3). Those mice injected with control serum showed no reduction of plaque-forming cells.

In further experiments the immunosuppressive activity of these sera was also demonstrated with a second antigen, horse red blood cells, which is serologically non-cross-reactive with SRBC. The immunosuppressive activity was found to be due to immunoglobulin since incubating the sera with goat anti-rabbit Ig-serum removed the activity (data not shown).

The possibility that antibody directed against a non-viral cellular antigen is responsible for the observed immunosuppressive effect is highly unlikely for several reasons. As the rabbit antisera did not react with normal rabbit SIRC cells by cytotoxicity or by fluorescence, a contaminating antigen of rabbit origin is unlikely. A mouse cellular antigen is ruled out as the only mouse antigens present in the infected rabbit cell line are viral gene products of the integrated mouse virus (barring transduction of non-viral mouse genes by the virus). Most importantly, virus grown in a third species, mink, also fully removed the activity by absorption.

There seem to be three possible explanations of the mechanism by which our antisera exert this immunosuppressive effect. First, the effect is due to complement-dependent cytotoxicity directed against lymphocytes

Table 3 *In vivo* immunosuppressive activity of antiserum against mitogen-induced xenotropic C-type virus

Expt no.	Serum (dilution) injected	PFC per 10 ⁷ spleen cells*	% Inhibition
1	Control serum	38,400 ± 1,700	—
	Antiserum	9,450 ± 540	75
2	None	28,900 ± 1,400	—
	Antiserum	5,950 ± 470	79
	1:2	4,430 ± 520	84
	1:4	5,480 ± 350	81
	1:8	8,480 ± 480	71
	1:16	11,030 ± 650	61

BALB/c mice aged 8–15 weeks were immunised by one i.p. injection of 5×10^8 SRBC. Antiserum or control serum (0.2 ml per mouse) was injected intravenously immediately after antigen administration. The animals were killed after 4 d and direct plaque forming cells (PFC) were assayed from spleen cells.

*Average of quadruplicate values from spleens of two individual mice. Values are given ± s.e.m.

participating in the anti-SRBC response. This seems unlikely, as the sera were not cytotoxic for spleen cells in a cytotoxic test using rabbit complement. Cytotoxicity on the level of the plaque-forming cells or its precursors also seems unlikely since the immunosuppressive activity was only observed when the antiserum was injected within 2 d after SRBC injection. Later injections during the 4-d immunisation period had no effect. A second possibility is that viral antigen is in close proximity to a membrane structure necessary for the immune response, for example, a receptor. Binding of antibody would then lead to steric hindrance of the receptor function. Finally, viral antigen itself may be required on the membrane. Here it could, for example, play a receptor-like role in cell-cell interaction. Blocking of the antigen therefore would lead to immunosuppression. While this last explanation is consistent with our working hypothesis, it is clear that further studies are necessary if a functional link between endogenous C-type viruses and the immune system is to be established.

These results show that antibody directed against endogenous xenotropic C-type viral antigens represents a new and interesting principle of immunosuppression. Work to identify the target cells of the antisera, the nature of the viral antigen and the mechanism of the immunosuppressive effect is in progress.

Development of improved cholera vaccine based on subunit toxoid

THE cholera vaccines now available consist of killed vibrios, and give rise to only limited protection of short duration¹. The finding that the excessive diarrhoea in cholera is due to the action on the small intestine epithelium of an exotoxin produced by the vibrios^{2,3} has focused attention on the potential of toxoid for improved immunoprophylaxis. The development of a suitable toxoid has met with great difficulties, however. Formalin toxoid, although reasonably antigenic, proved unsatisfactory because of reversion to toxicity⁴. Glutaraldehyde toxoid was stable but poorly immunogenic which explains its low efficacy in a recent field trial⁵. We describe here the development and properties of a subunit cholera toxoid, the nature of which eliminates the risk of reversion to toxicity. The high protective immunogenicity observed in experimental animals gives promise that addition of this toxoid to the conventional vaccine will result in a significantly improved immunoprophylactic agent against cholera.

Different *Vibrio cholerae* strains, irrespective of their serotype, produce an immunologically identical exo-enterotoxin⁶. The toxin contains two types of non-covalently linked subunits, one heavy (H or A; molecular weight (MW) about 28,000) and five or six light ones (L or B, MW about

Fig. 1 Preparation of L-subunit toxoid from purified cholera toxin. The toxin (about 10 mg in 1–2 ml) was diluted with 20% concentrated formic acid to give a 5% final concentration of the acid. After incubation for 1 h, the sample was filtered (at room temperature) through a 2.5 × 87.5-cm Sephadex G-100 column equilibrated as well as eluted (25 ml h⁻¹) with 5% formic acid. Consecutive 4-ml fractions were collected and their light absorbance at 280 nm determined. The diagram shows the protein elution profile from a typical experiment, in which 8.5 mg toxin was processed. Two distinct peaks emerge, the first representing isolated subunit H and the second, bigger one subunit L. The amounts of applied toxin and eluted subunits were estimated from the absorbance values using the $A_{280}^{1\%}$ coefficients¹ 11.4 for the toxin, 15.1 for subunit H and 9.56 for subunit L fractions. The fractions hatched in the diagram were pooled, dialysed against PBS (0.05 M phosphate, 0.14 M sodium chloride, pH 7.2) at 4°C for 48 h, and then used as L-subunit toxoid. The inserted photograph illustrates the results obtained on testing samples of individual gel filtration fractions by sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS-PAGE). The samples were lyophilised, redissolved in 2% SDS–8M urea solution, incubated at 53°C for 20 min and then processed by SDS-PAGE⁷. Every second fraction from number 48 to 72 was tested. In addition, cholera toxin (CT) was included in two positions as a reference for the migration of subunits H and L. The arrow indicates start line and + the anode direction.

Table 1 Protective immunity and serum antibody titres in rabbits after immunisation with L-subunit and glutaraldehyde toxoids

Dose of toxoid (µg)	No. of animals	Protection factor Live vibrios	Crude toxin	Serum antitoxin titre
L-subunit toxoid				
30	7	18	5.0	400,000
15	4	10	2.5	130,000
10	8	3.2	1.8	100,000
7.5	5	1.3	1.4	25,000
Glutaraldehyde toxoid				
30	4	5.0	1.6	20,000
15	4	0.7	1.1	10,000

New Zealand rabbits weighing 1.2–1.5 kg at the onset of immunisation were used. The L-subunit toxoid was prepared as described in Fig. 1. The glutaraldehyde toxoid²¹ (Wyeth; lot 20101) was provided by Dr C Miller of NIH. The antigens were injected s.c. without adjuvant in two 0.5 ml portions above the right and left posterior legs twice with a 2-week interval. A similar number of control rabbits as in the immunised group were injected with phosphate-buffered saline (PBS). Five days after the booster injection the immunised and control animals were tested for susceptibility to experimental cholera. In each animal 21 about 5-cm long segments of the small intestine were ligated. Into each loop was injected graded doses (in 1-ml volumes) of live cholera vibrios (strain 569B) or crude cholera toxin (*V. cholerae* 569B culture filtrate, NIH lot 4493G). Five doses of bacteria (10⁵–10⁹) and crude toxin (0.1–10 mg) were tested in duplicate at randomly chosen positions. The remaining loop was injected with 1 ml PBS and served as a negative control. Fluid accumulation in the intestinal segments was measured after 15–18 h as ml fluid per cm intestine and ED₅₀ (dose of bacteria or toxin producing half-maximal intestinal filling) determined for each group of animals²⁰. The protective effect of immunisation—the protection factor—was estimated as the ratio between the group ED₅₀ values for immunised and concurrently tested control animals. Serum antitoxin titres were determined by the enzyme-linked immunosorbent assay (ELISA)²² on serum samples, pooled in each group, collected on the day of the intestinal challenge.

11,000 each)^{7–12}. The L subunits are responsible for the binding of toxin to the cell membrane but not for the subsequent activation of adenylate cyclase. Conversely, the H subunit is essential for toxicity but, because of its inability to bind to cells, it is inactive in the absence of L subunits^{13,14}. The two types of cholera toxin subunits are immunologically unrelated¹³. The subunits also differ markedly in immunogenicity so that immunisation with intact toxin gives rise to antisera which always react strongly with the L subunit but only irregularly and at low titre with subunit H. Furthermore, isolated anti-H subunit antibodies have very low cholera toxin-neutralising capacity in contrast to antibodies reacting with subunit L¹⁵. Immunological protection by means of cholera antitoxin thus probably results from prevention of toxin binding to intestinal cell receptors rather than from interference with the 'active site' on the effector subunit. We have therefore directed our efforts to the preparation of pure L subunits and reaggregation of these subunits. Theoretically this should yield an almost ideal toxoid for immunisation, since the elimination of subunit H excludes the risk of reversion to toxicity without causing any significant loss of protective capacity.

The method for preparation of L-subunit toxoid was based on the fact that the two types of subunit in cholera toxin can be isolated by gel filtration of toxin in acidic buffer⁷. Highly purified toxin, prepared essentially according to Finkelstein *et al.*¹⁶, was treated with formic acid and the dissociated subunits separated on Sephadex G-100 (Fig. 1). This resulted in an almost quantitative isolation of the toxin L subunits in pure form. In five different experiments the yield of L was 90–93% and contamination with subunit H could be excluded at a level of 0.2% (w/w) using sensitive immunological methods. As determined with the rabbit skin¹⁷ and mouse thymocyte cyclic AMP accumula-

Table 2 Increased duration of protection by immunisation with toxoid or toxoid-enriched cholera vaccine

	Protection factor				Serum antibody titres			
	Day 5		Day 21		Day 5		Day 21	
	Live vibrios	Crude toxin	Live vibrios	Crude toxin	LPS	Toxin	LPS	Toxin
Cholera vaccine (4×10^9 killed vibrios)	10	1.1	2.0	1.0	120,000	<500	300,000	<500
L-subunit toxoid (10 μ g)	3.2	1.8	13	3.0	<500	100,000	<500	200,000
Cholera vaccine + L-subunit toxoid	80	2.1	90	3.0	100,000	400,000	500,000	600,000

Groups of 8–12 rabbits were immunised according to the schedule described in Table 1. Twelve concurrently PBS-injected rabbits served as controls. Half of the animals in each group were challenged with live vibrios or crude toxin in alternating loops 5 d and the others 21 d after the booster immunisation. The protective effect of immunisation (the protection factor) and the serum antibody titres against *V. cholerae* lipopolysaccharide (LPS) and enterotoxin were determined as in Table 1.

tion assays¹⁸, all batches of L-subunit toxoid had less than 0.1% of the toxicity of intact toxin.

Radial immunodiffusion tests (Mancini) suggested that the L subunits in the toxoid, with retention of their full reactivity with antibody, were aggregated to a complex with a diffusion rate similar to that of native toxin. This aggregation was demonstrated directly by thin-layer gel filtration in Sephadex G-200 superfine¹⁹. The L-subunit toxoid migrated as a single component with a rate faster than that of subunit H and there was no detectable toxoid protein filtering at the rate which would be expected for the individual L subunits.

The toxoid was usually kept frozen in aliquots at -30°C , and storage for more than 18 months did not result in detectable changes according to the immunological, physicochemical and biological criteria mentioned above. In the presence of 0.01% merthiolate the toxoid has been stable at $4^\circ\text{--}8^\circ\text{C}$ for more than 6 months.

The immunogenicity of the L-subunit toxoid was studied in rabbits and compared with that of the recently field tested glutaraldehyde toxoid. Two subcutaneous (s.c.) immunisations with 10 μ g of L-subunit toxoid in each injection induced significant protection (Table 1). The effect in-

creased with increasing amounts, so that 30 μ g gave an approximately 20-fold increased resistance to live vibrio challenge and 5-fold protection against challenge with toxin. The glutaraldehyde toxoid was much less effective and also gave rise to lower serum antibody titres than the L-subunit toxoid (Table 1). Adsorption to aluminium phosphate did not significantly enhance the protective immunogenicity of the L-subunit toxoid as tested with 10 μ g of toxoid on 0.034 mmol of carrier. No side-effects of immunisation were observed in any instance.

V. cholerae enterotoxin and cell wall lipopolysaccharide (LPS) has been shown to induce a synergistic protective immunity against experimental cholera infection²⁰. In agreement with this, combinations of L-subunit toxoid and conventional cholera vaccine or purified LPS were found to induce a level of protection against intestinal challenge with live vibrios which equalled or exceeded the product of the immunity attained with the individual antigens (Fig. 2). Challenge in alternate loops with crude toxin (not shown) revealed that the somatic antigens neither gave rise to any antitoxic immunity nor enhanced the efficacy of the toxoid component in protection against toxin. Furthermore, the serum antibody titres induced by the antigens in the mixture

Fig. 2 Synergistic protective effect of immunisation with combinations of *V. cholerae* somatic antigen and L-subunit toxoid. Three experiments are presented, each comprising four groups of four to eight rabbits. One group received PBS injections only, and the others were immunised according to the schedule described in Table 1 with, respectively, somatic antigen (killed *Vibrio cholerae* vaccine (C.V.) in two doses, or purified *V. cholerae* lipopolysaccharide (LPS)), L-subunit toxoid (L-tox.), or the somatic antigen and toxoid in mixture. Five days after immunisation intestinal challenge with graded doses of live vibrios was performed as described in Table 1 and ED₅₀ was determined for each animal. The means \pm s.e.m. of the individual ED₅₀ values of bacteria are shown for each group of rabbits. The figures on top of the bars are the ratios between the mean ED₅₀ for immunised animals and the mean ED₅₀ for the PBS-injected control rabbits, that is, the fold-increase protection achieved by immunisation. The cholera vaccine (National Bacteriological Laboratory, Stockholm) contained equal numbers of phenol-killed Inaba and Ogawa vibrios. The LPS was purified from *V. cholerae* 569B by means of hot phenol-water extraction and ultracentrifugation²¹.

did not differ significantly from those produced by the respective antigens alone. These data indicate that the synergistic protective effect obtained by immunisation with toxoid and somatic antigen in combination is not due to enhancement of the antitoxic and antibacterial immune responses in themselves. Instead, it probably results from the interference of the immunity with two separate events of pathogenic importance, that is, the mucosal adhesion of cholera vibrios and binding of enterotoxin to specific membrane receptors¹⁸.

As in humans, the conventional vaccine gave rise only to short-term protective immunity in rabbits. The immunity against challenge with live vibrios decreased markedly between day 5 and 21 after the booster injection, in spite of a slight increase in the serum anti-LPS antibody titre (Table 2). In contrast, a combination of L-subunit toxoid and vaccine gave rise to immunity which rather increased during this period. This was probably due to a sufficient rise in the antitoxic immunity induced by the toxoid component to compensate for the rapid decrease in antibacterial immunity, as immunity induced by L-subunit toxoid alone increased substantially from day 5 to 21 (Table 2).

In conclusion, a subunit cholera toxoid having no risk of reverting to toxicity has been developed. Vaccination with a mixture of this toxoid and killed vibrios should result in more effective, longer lasting immunity against cholera than that given by immunoprophylactic agents used previously. Studies in progress suggest that inexpensive large-scale production may be possible by preparing the subunit toxoid from crude toxin preparations.

We thank Dr Charles Wadsworth for performing the thin-layer gel filtration analyses. This work was supported by the Swedish Medical Research Council and the WHO.

Polymorphism of apolipoprotein E and occurrence of dysbetalipoproteinaemia in man

PRIMARY dysbetalipoproteinaemia (broad- β disease, hyperlipoproteinaemia type III) is a familial disorder of plasma lipoprotein metabolism associated with xanthomatosis and early onset of severe atherosclerotic vascular disease¹⁻⁴. A defect in the catabolism of triglyceride-rich lipoproteins probably underlies the accumulation of atypical cholesterol-rich lipoproteins (very low density β lipoproteins, ' β -VLDL') in the S_{12-400} density fraction⁵⁻⁷. The disorder is assumed to be rare⁸ and we have provided evidence for an autosomal recessive mode of inheritance^{9,10}. Patients show a variant of one major protein component (Apo E) of VLDL^{11,12}. Apo E is a glycoprotein of molecular weight $\sim 39,000$ that splits into three main bands designated E-I ($pI \sim 5.3$), E-II ($pI \sim 5.4$) and E-III ($pI \sim 5.55$) in isoelectric focusing¹³. The Apo E variant is characterised by a deficiency of Apo E-III in triglyceride-rich lipoproteins. We report here that Apo E shows a genetic polymorphism determined by two alleles *Apo Eⁿ* and *Apo E^d*. About 1% of the German population is homozygous for the allele *Apo E^d* and exhibits Apo E-III deficiency. All individuals of this genotype have a primary dysbetalipoproteinaemia but not necessarily hyperlipidaemia. This is therefore the most frequent monogenic dyslipoproteinaemia known in man.

A simple method for the detection of Apo E patterns without ultracentrifugation that allows the selective recognition of patients with dysbetalipoproteinaemia in a hyperlipidaemic group (refs 9, 11 and unpublished work of G.U., M.H., G. Mühlfellner, N. Pruin and K. H. Vogelberg) has been applied to evaluate Apo E patterns in 490 blood donors from Marburg/Lahn. VLDL was precipitated from 1 ml of serum by addition of 50 μ l of a 5% aqueous heparin solution and 50 μ l 2 M $MgCl_2$. Crude VLDL was isolated by low-speed centrifugation, resuspended in 0.5 ml 0.02 M Tris-HCl, 0.1 M NaCl, 0.017 M sodium citrate pH 7.7 and reprecipitated by addition of 25 μ l 2 M $MgCl_2$. VLDL was extracted with chloroform-methanol, 2:1 (v/v). Apo VLDL was solubilised

Fig. 1 Analytical isoelectric focusing (pH 3.5-10 in polyacrylamide gels containing 6 M urea) of nine individual apo-VLDL preparations demonstrating the different Apo E phenotypes Apo E-N (a, c, g), Apo E-ND (b, d, e, f) and Apo E-D (h, i). The additional cathodic band ($pI \sim 5.75$) in gels c, d, f represents a further independent genetic marker (Apo E-IV(+)-variant) that had a frequency of 26.9% in the population sample studied and is transmitted as an autosomal dominant trait¹⁷ (see also Fig. 3).

Fig. 2 Distribution of Apo E patterns according to Apo E-II/E-III ratios (densitometric areas) in individual apo VLDL samples ($n=181$) that have been evaluated by scanning densitometry. Each square represents one individual. Proband with features of dysbetalipoproteinaemia are marked in black. Insert: representative densitometric scans of stained focusing gels demonstrating the three common Apo E phenotypes Apo E-N (a), Apo E-ND (b) and Apo E-D (c). Only the Apo E region is shown. The pI values of the individual bands determined by flat bed isoelectric focusing in granulated gels were ~ 5.3 (E-I), ~ 5.5 (E-II) and ~ 5.55 (E-III). (U. Beisiegel and G.U., unpublished) and differed slightly from those determined in the analytical polyacrylamide gels¹³.

in 200 μ l 0.02 M Tris-HCl, 8 M urea, pH 8.2 and subjected to isoelectric focusing in a pH gradient from 3.5–10 in polyacrylamide gels containing 6 M urea. Protein bands were stained with coomassie brilliant blue and evaluated by scanning densitometry.

Three phenotypes, Apo E-N, Apo E-ND and Apo E-D (E-III deficiency pattern) were differentiated on the basis of the Apo E-II/E-III ratios (Figs 1 and 2). The ratio was 0.40 ± 0.07 for phenotype Apo E-N, 1.02 ± 0.25 for phenotype Apo E-ND and 9.07 ± 4.48 for phenotype Apo E-D. No overlap was observed between the distinct groups in this study.

In control experiments VLDL was isolated by conventional preparative ultracentrifugation from individuals of phenotypes Apo E-D ($n=5$) and Apo E-ND ($n=51$) and from a control group of the same size. All individuals were in a fasting state. In all cases the previous diagnosis was confirmed. The demonstration of Apo E phenotypes is therefore independent of the method used for isolation of VLDL. The frequencies of the three common Apo E phenotypes were 83.3% for Apo E-N, 15.7% for Apo E-ND and 1.0% for Apo E-D.

Apo E patterns were determined in three kindreds of probands of phenotype Apo E-D (Fig. 3). The segregation of Apo E phenotypes among children from different parental matings is consistent with a simple Mendelian mode of transmission where two alleles determine the three phenotypes Apo E-N, Apo E-ND and Apo E-D. Considered together, the population and family data show that, in man, genetic polymorphism of apolipoprotein E is governed by two common autosomal alleles *Apo Eⁿ* (frequency 0.9112) and *Apo E^d* (frequency 0.0888). The observed frequencies of the three phenotypes are in good agreement with those expected according to Hardy-Weinberg's law. No significant differences between females ($n=144$; $Apo E^n=0.9201$) and males ($n=346$; $Apo E^n=0.9075$) were observed.

The frequency of the allele *Apo E^d*, however, was unexpectedly high. We therefore investigated whether the

homozygous probands of phenotype Apo E-D detected had dysbetalipoproteinaemia. Analysis of the composition of the main lipoprotein fractions of all five probands in comparison with a control group of 94 subjects of phenotypes Apo E-N ($n=43$) and Apo E-ND ($n=51$) showed that they in fact represented a biochemically distinct group with abnormalities in their lipoprotein spectrum characteristic of dysbetalipoproteinaemia. These were (1) an abnormal quantitative distribution of lipoproteins (demonstrated by density gradient centrifugation) with reduced levels of LDL and elevation of VLDL and also intermediary density lipoprotein levels (Fig. 4); (2) a markedly reduced or absent LDL band in polyacrylamide gel electrophoresis (Fig. 5); (3) presence of ' β -VLDL' in the $d < 1.006$ g ml⁻¹ fraction in the ultracentrifuge (Fig. 5) and (4), an increase in the relative and absolute concentrations of cholesterol in VLDL (Table 1). Thus all probands had dysbetalipoproteinaemia according to the 'floating- β test' and also according to at least one of the lipid-chemical definitions recently proposed for the disorder^{14,16}. However, none had hypercholesterolaemia and only three had mild hypertriglyceridaemia: total serum cholesterol levels

Fig. 3 Pedigrees of three kindreds demonstrating the segregation of Apo E phenotypes. Propositi were a A.W. (Wa-kindred); b, B.Z. (Z-kindred) and c, M.B. (Ba-kindred) (see Table 1).

Fig. 4 Profiles of lipoprotein cholesterol after density gradient centrifugation of 4 ml of serum from a normolipidaemic control subject (a), a hyperlipidaemic proband of phenotype Apo E-D (b), and a normocholesterolaemic proband of phenotype Apo E-D (c). Centrifugation was performed in a SW-41 rotor at 40,000 r.p.m. for 24 h at 4 °C. The gradient was from 1.006 g ml⁻¹ to 1.21 g ml⁻¹ KBr and prepared according to Redgrave *et al.*¹⁸. Fractions were collected from below and cholesterol determined with the enzymatic method of Roeschlau¹⁹. — — —, Absorbance at 405 nm of 3,5-diacetyl-1, 4-dihydrolutidine the endproduct in the enzymatic test for cholesterol. — — —, Density.

Fig. 5 Left: Discontinuous electrophoresis in polyacrylamide gels of 3.75% monomer concentration of sera prestained with sudan black B²⁰ from two controls of phenotype Apo E-N (a, b) and two probands of phenotype Apo E-D (c, d). The poor staining of the HDL-band in gels c and d indicated a decrease in the concentration also of this component but was not seen in all individuals of phenotype Apo E-D. Chyl, Chylomicrons. Right: Agarose gel electrophoresis of sera (a), VLDL (b) and fraction d > 1.006 g ml⁻¹ (c) from a control subject (A) and a proband of phenotype Apo E-D (B). Staining sudan black B.

were abnormally low in the three probands under age 30 yr. From a study of subjects with primary hypocholesterolaemia where about 10% were of phenotype Apo E-D (compared with 1% in the general population observed in this study) we have additional evidence that young individuals of phenotype Apo E-D represent a novel genetic form of hypocholesterolaemia with hypobetalipoproteinaemia (G.U., H. Kaffarnik, and N. Pruin, in preparation). According to the data presented here the gene frequency for dysbetalipoproteinaemia (including hypo-, normo- and hypercholesterolaemic subjects) is 0.089 in the German population sample studied. This high frequency explains the occurrence of vertical transmission of dysbetalipoproteinaemia^{2,4,8} as pseudo-dominance (see Z-kindred in Fig. 2 and refs 9, 10).

In contrast to the high frequency of dysbetalipoproteinaemia in the population, individuals of phenotype Apo E-D that have gross hyperlipidaemia and xanthomatosis seem to be rare. Studies in progress in our laboratory indicate that additional mutant genes for other forms of familial dyslipoproteinaemia (familial combined hyperlipidaemia, familial hypertriglyceridaemia, familial hypercholesterolaemia) are operating in those patients that have

Table 1 Clinical data on the five probands of phenotype Apo E-D

Human serum lipoproteins activate adipocyte plasma membrane adenylate cyclase

BROWN and Goldstein¹ and Stein *et al.*², have shown evidence for the role of a specific cell surface receptor in the binding and catabolism of serum low-density lipoproteins (LDL) by cultured human fibroblasts. This receptor does not seem to be unique to fibroblasts however, since it has been shown that circulating human lymphocytes³, human fat cells⁴ and cultured smooth muscle cells⁵ may also bind LDL; also, binding sites for LDL and very low density lipoproteins (VLDL) seem to be present in crude membrane preparations from various organs and tissues of the pig⁶. These findings suggest that lipoprotein receptors are ubiquitous in mammalian cells and raise the possibility that occupancy of such surface binding sites might modify some aspect of membrane function. Evidence for an alteration of membrane function by lipoproteins was recently reported by Shore and Shore⁷, who observed that human serum VLDL and LDL were capable of specifically activating the human erythrocyte membrane Mg²⁺-ATPase.

The plasma membrane of the adipocyte is intimately involved in lipid metabolism, particularly as a result of its role in the hormone-sensitive adenylate cyclase-triglyceride lipase system⁸. Since the properties and enzyme activities of this membrane may be modified by the components of its external environment, it seemed possible that circulating lipoproteins might affect its function. We describe here the activatory effect of human serum lipoproteins on the adenylate cyclase system of plasma membranes from human and rat adipocytes.

Adipocytes were isolated by collagenase digestion⁹ from the epididymal fat pads of male Wistar rats (150-180 g),

Fig. 1 Adenylate cyclase activity of plasma membranes from rat and human adipocytes as a function of serum lipoprotein concentration. The final incubation medium (50 μl) for the adenylate cyclase assay contained 0.2 mM [α -³²P]-ATP (0.5 μCi) (Radiochemical Centre, Amersham), 5 mM MgSO₄, 1 mM cyclic AMP, 1 mM EDTA, 1 mM dithiothreitol, 50 mM Tris-HCl (pH 7.8), an ATP-regenerating system consisting of 10 mM phosphocreatine (di-Tris salt, Sigma) and 0.5 IU creatine phosphokinase (Calbiochem). Plasma membranes from rat adipocytes (2 μg protein (a)) or from human adipocytes (1.5 μg protein (b)) were added to the reaction mixture (containing 0.2 mM ATP). Preincubation was carried out for 15 min at 30 °C in the presence of LDL (○) or VLDL (●); lipoprotein samples were added in a volume of 10 μl. At the end of the preincubation period, labelled ATP was added and the reaction allowed to proceed for 10 min at 30 °C. The accumulation of labelled cyclic AMP was linear as a function of time. The reaction was terminated according to White¹³ and the ³²P labelled-cyclic AMP was isolated by column chromatography on neutral alumina¹³. Each determination was performed in duplicate. Results are expressed as pmol cyclic AMP formed per min per mg protein. The amount of ATP present at the end of the incubation was determined by thin-layer chromatography on polyethyleneimine-cellulose developed in 1 M LiCl. In these conditions, residual ATP amounted respectively to 92% and 96% of its original concentration, in the absence and in the presence of 260 μg VLDL protein per ml. The product formed in the reaction mixture was identified as authentic ³²P-cyclic AMP by three procedures: (1) it migrated together with authentic cold cyclic AMP on cellulose plates developed in 1 M ammonium acetate and 95% ethanol (1/2.5, v/v); (2) the product of the reaction had the same specific activity when isolated either by the routine method described above or after two chromatographic steps through Dowex AG 50 W-X8 (H⁺ form) and neutral alumina¹⁴; and (3) 90% of the ³²P labelled product isolated in the presence or the absence of lipoproteins in the assay medium of adenylate cyclase was hydrolysed by 3', 5'-cyclic AMP phosphodiesterase from beef heart (Sigma, 20 μg; 20 min incubation at 30 °C).

Table 1 Activation by human serum VLDL of adenylate cyclase from rat adipocyte plasma membranes at several ATP and Mg^{2+} concentrations

ATP (μM)	Adenylate cyclase activity (pmol cyclic AMP per mg protein per min \pm s.e.)*					
	Mg^{2+} (mM)					
	1		5		50	
	0	VLDL (200 μg ml $^{-1}$)	0	VLDL (200 μg ml $^{-1}$)	0	VLDL (200 μg ml $^{-1}$)
10	2.8 \pm 0.6	6.6 \pm 0.4 (137)	16.6 \pm 1.2	27.5 \pm 0.9 (66)	13.1 \pm 0.2	20.1 \pm 0.6 (53)
50	6.8 \pm 0.7	13.6 \pm 1.5 (99)	40.2 \pm 1.6	68.5 \pm 1.5 (70)	54.5 \pm 0.1	79.5 \pm 0.1 (46)
200	6.6 \pm 2.2	7.6 \pm 0.6 (15)	61.3 \pm 8.8	96.7 \pm 6.2 (58)	127.8 \pm 2.1	181.5 \pm 0.2 (42)

Rat fat cell membranes (1.5 μg of protein) were incubated in the experimental conditions described in the legend to Fig. 1. The numbers in parentheses represent percentage cyclase activation relative to the basal level.

* Standard error of triplicate determinations.

while human adipocytes were prepared from subcutaneous fat obtained at surgery. Plasma membranes were separated as previously described¹⁰. Lipoproteins were isolated at 5 °C from the sera of normolipidaemic adult donors by sequential preparative ultracentrifugation (see Havel *et al.*¹¹); the detailed conditions have been previously outlined¹². The density intervals used for the various fractions were: VLDL, $d < 1.006$ g ml $^{-1}$; LDL, d 1.024–1.045 g ml $^{-1}$ and high-density lipoprotein (HDL), d 1.080–1.210 g ml $^{-1}$. All fractions were extensively dialysed at 5 °C against a solution containing 150 mM NaCl, 0.5 mM Na₂EDTA and 5 mM Tris-HCl at pH 7.5.

Human serum VLDL and LDL stimulated the basal activity of adenylate cyclase from human and rat adipocyte plasma membranes (homologous and heterologous systems respectively) in a dose-dependent manner (Fig. 1). Such activation was a saturating phenomenon; half-maximal activation occurred in the concentration range of 50–100 μg VLDL or LDL protein ml $^{-1}$ (Fig. 1). The stimulation of basal adenylate cyclase activity by VLDL was more potent than that elicited by LDL. The effect of HDL on enzyme activity was always inferior to or equal to that of LDL (data not shown).

The degree of activation of the adenylate cyclase system in a given membrane preparation varied with VLDL isolated from different sera. For example, the same human membrane preparation studied with three separate VLDL samples (protein concentration 150 μg ml $^{-1}$), elicited activations amounting to 250%, 1,400% and 1,970%, respectively of that of the basal adenylate cyclase activity determined in standard conditions (for details see Fig. 1 legend). Such observations may probably be attributed to variations in the relative proportions of the different particle species present in each VLDL fraction. A more constant but lower degree of stimulation by human VLDL was found in experiments with plasma membranes from rat

adipocytes (78 \pm 13%, mean value \pm s.e.m., $n = 6$ for 4 membrane preparations), that is, in the heterologous system.

The effect of substrate concentration on cyclase stimulation by VLDL was examined by variation of the ATP concentration in the range 10–200 μM at several Mg^{2+} concentrations in the assay medium. The results indicated a strong substrate ($MgATP$) dependency of the cyclase activation by VLDL which occurred at an Mg^{2+} concentration of 1 mM: at higher Mg^{2+} concentrations, the extent of enzyme activation by VLDL was essentially unchanged in the range 10–200 μM ATP (Table 1).

The possibility that lipoproteins could also modify the cyclic AMP-phosphodiesterase activity in the membrane preparations was investigated. The adenylate cyclase activity measured in the presence of 1 mM cyclic AMP was only 10–15% above that observed in its absence and the extent of cyclase activation by lipoproteins was unaffected by the presence of cyclic AMP. Also, additional experiments indicated that VLDL were without effect on the membrane phosphodiesterases of low and high K_m , whose activities were measured by the method of Thompson and Appleman¹⁵ (data not shown). We conclude therefore that the increased synthesis of ^{32}P -labelled cyclic AMP which we have observed results specifically from an effect of serum lipoproteins on the adenylate cyclase system.

Activation by serum lipoproteins of adenylate cyclase in both homologous and heterologous experimental systems also occurred when the enzyme was maximally stimulated by 0.1 mM adrenaline (bitartrate), by 10 mM fluoride ion or by 0.1 mM guanylyl (β,γ -methylene)-diphosphonate (Gpp(CH₂)p) (Table 2). These findings show that serum lipoproteins do not seem to modify the responsiveness of the cyclase system to hormones or other effectors; similar effects have been reported in other systems following the addition of polycationic peptides¹⁶ or after limited proteolysis¹⁷. Our present observations are, however, consistent with the sug-

Table 2 Effect of human serum VLDL and LDL on adenylate cyclase activity in human and rat fat cell membranes stimulated by adrenaline, fluoride ion and Gpp(CH₂)p

Plasma membranes	Addition	Adenylate cyclase activity (pmol cyclic AMP per mg protein per min \pm s.e.)*			
		None (basal)	Adrenalin (0.1 mM)	NaF (10 mM)	Gpp(CH ₂)p (0.1 mM)
	0	2.5 \pm 0.5	3.5 \pm 0.6	30.3 \pm 7.2	10.1 \pm 1.8
Human	VLDL	25.8 \pm 1.5	28.6 \pm 3.2	220.0 \pm 22.6	81.0 \pm 0.9
	LDL	11.8 \pm 1.5	16.0 \pm 0.8	158.0 \pm 34.0	76.0 \pm 2.6
Rat	0	92.0 \pm 2.3	391.0 \pm 31.0	434.0 \pm 14.3	229.0 \pm 10.4
	VLDL	175.0 \pm 1.6	593.0 \pm 18.2	874.0 \pm 52.1	350.5 \pm 8.5
	LDL	112.3 \pm 1.5	508.0 \pm 21.2	n.d.	n.d.

The experimental conditions were as described in the legend to Fig. 1, except that incubation was performed at 37 °C; the ATP and Mg^{2+} concentrations were 0.2 mM and 5 mM respectively; the amount of membrane protein incubated was 2.2 μg (rat) and 1.5 μg (human). The concentration of lipoproteins was 200 μg protein ml $^{-1}$.

gestion that VLDL transform the catalytic site of the cyclase into an activated state, in which it retains its susceptibility to stimulation by various effectors.

The mechanism involved in the observed activation by serum lipoproteins of the adenylate cyclase system in adipocyte plasma membranes remains indeterminate. The effect may, however, be dependent on some aspect of the native lipoprotein molecule, since isolated phospholipids (egg yolk lecithin and lysolecithin, added at concentrations equivalent to their content in native VLDL) lead to inhibition of the adenylate cyclase activity in fat cell membranes (preliminary observations). The observed activation of the adenylate cyclase system by VLDL might occur via an intermediate coupling step, involving lipoprotein binding sites on the adipocyte plasma membrane. Thus it seems likely that the apoprotein would be directly concerned, as has been demonstrated in the activation of the erythrocyte membrane Mg^{2+} -ATPase by VLDL (ref. 7). Alternatively, the activation of plasma membrane adenylate cyclase might occur by virtue of a physicochemical interaction between the serum lipoprotein particles themselves and plasma membranes. Thus, evidence has been provided for the exchange and transfer of cholesterol and of phospholipids between serum lipoproteins and a variety of cell membranes (for a review see ref. 18). Such processes, which may occur *in vivo*, may maintain or modify membrane fluidity and are thus implicated in the modulation of the immediate environment of the cyclase system; several lines of evidence indicate that the catalytic activity¹⁸⁻²¹ and hormone responsiveness^{20, 22-25} of the adenylate cyclase system are strongly dependent on the nature of its surrounding lipids.

Papahadjopoulos²⁶ has suggested that serum β -lipoproteins may regulate the activity of several key membrane-bound enzymes, such as the $(Na^+ + K^+)$ ATPase and adenylate cyclase. This hypothesis is consistent with the present observations which indicate that serum lipoproteins may stabilise or modify the adenylate cyclase system of fat cell membranes.

Dominique Lagrange and Françoise Lecot gave excellent technical assistance. Nelly Scharapan kindly prepared the typescript. We gratefully acknowledge Dr M. H. Laudat for her interest in this work. We thank Professor D. Mellièrè for provision of human fat samples. This study was supported by a grant from the Délégation Générale à la Recherche Scientifique et Technique. Interaction of a fluorescent probe with acetylcholine-activated synaptic membrane

GRÜNHAGEN and Changeux have shown^{1,2} that *Torpedo* membrane fragments stained with the antimalarial, quinacrine, show a rapid increase in fluorescence after mixing with cholinergic agonists (see ref. 3). These authors suggest that the fluorescence intensity of quinacrine associated with cholinergic receptors increases during the transition of the receptor from its resting to its active state. We report here an electrophysiological analysis of the kinetic behaviour of the postsynaptic membrane of intact vertebrate muscle fibres treated with quinacrine. The kinetic data from the fluorescence and electrophysiological experiments show remarkable parallels, and we suggest that both experimental procedures reveal the binding of quinacrine to the activated receptor.

The experiments were carried out at room temperature (20-23 °C) on frog endplates using the voltage jump relaxation technique⁴⁻⁷. An endplate was voltage-clamped using a conventional two-electrode arrangement. The endplate current induced by iontophoretic or bath application of acetylcholine (ACh) or carbachol was measured either using extracellular focal recording⁴, or as the total current after subtracting current flowing in the absence of agonist⁵. The first set of experiments was performed using focal current recording and iontophoretic ACh application. The focal recording method yields very small currents recorded during voltage steps in the absence of agonist (upper traces in Fig. 1a, b, c). During ACh action but before treatment with quinacrine, control relaxations were obtained by stepping the membrane potential to a new level and observing the resulting changes in agonist-induced current (Fig. 1a). Following a step hyperpolarisation (marked by a downward arrow) the agonist-induced current jumps very rapidly from its previous steady level to the new level expected from the change in driving force on those channels that are already open just before the jump. The current then increases exponentially to a new steady level, as the ACh-evoked conductance increases from the equilibrium level appropriate to the original holding potential to the level appropriate to the potential during the jump. This conductance increase reflects opening of additional endplate channels. Over the range of agonist concentrations used in the present study, the normal open-close kinetics of the channel behave as if a single molecular inter-conversion takes place

The forward rate constant is increased by increasing the agonist concentration^{6,8} and the back rate constant is decreased by hyperpolarising the membrane⁹.

In the presence of 0.5 μ M quinacrine, the time course of the fast

Fig. 1 Effect of quinacrine ($0.5 \mu\text{M}$) on relaxations induced by rectangular voltage jumps (from -60 mV to -100 mV at the downward arrow, and back to -60 mV at the upward arrow) during the action of iontophoretically applied ACh at a voltage-clamped sartorius endplate. Membrane current was recorded as the potential difference between a Ringer-filled fire-polished micropipette placed on the nerve terminal and a similar reference micropipette nearby. Downward deflections represent inward membrane currents. In each pair of traces, the upper trace shows the negligible leakage current during voltage jumps in the absence of ACh. The lower traces show responses to jumps during ACh iontophoretic applications (the absolute vertical shift between the upper and lower traces does not indicate the absolute value of the ACh-induced current at -60 mV). *a*, Control in the absence of quinacrine; *b*, and *c*, in the presence of $0.5 \mu\text{M}$ quinacrine. The same agonist dose was applied in *a*, *b* and *c*. A short jump was applied in *a* and *b* (25-ms time calibration), and a long jump in *c* (1-s time calibration). The extra ACh current which normally develops during the step was greatly decreased in the presence of quinacrine. In *c*, an additional slow inactivation process reflecting desensitisation shows up as an inclined base line. Miniature endplate currents are visible in the left-hand traces.

increase in conductance following a step from -60 mV to -100 mV was little changed (Fig. 1*a**b*). The initial relaxation, however, was now followed by a slow decrease in current (Fig. 1*b*), and if the hyperpolarisation was maintained, the extra agonist-induced current fell back to a low level (Fig. 1*c*). Inactivation of agonist-induced current following a step hyperpolarisation was not seen in the absence of quinacrine in the conditions of the present experiments. On stepping back from -100 mV to -60 mV (upward arrows) there occurred, successively, a very fast ohmic decrease in current, a fast relaxational decrease in current and finally a slow increase in current (Fig. 1*b* and *c*). When applying ACh iontophoretically, the slow relaxation was not always exponential, probably because of local variations in agonist concentration or concurrent desensitisation.

The slow relaxation was then studied in more detail using bath agonist application, total current recording and a fixed quinacrine concentration of $1 \mu\text{M}$. In these conditions (Fig. 2), the slow relaxation, measured after subtracting currents flowing during the step in the absence of agonist, was exponential. Its time constant became smaller as the concentration of agonist (ACh or carbachol) was increased (Figs 2 and 3). The times for half decay of the slow relaxation for -60 mV to -140 mV jumps are shown as a function of agonist concentration in Fig. 3. Individual half-decay times ranged from 2 to 0.04 s . Higher concentrations of carbachol than of ACh were needed to give equal half-decay times.

Our results show that even at low concentrations, quinacrine profoundly modifies the normal kinetic behaviour of the cholinergic membrane, and that in steady-state conditions, it gives rise to a blocking effect more pronounced at more hyperpolarised potentials. This effect of quinacrine at the endplate strikingly resembles the action of procaine on *Aplysia* neurones¹⁰, and may thus reflect the local anaesthetic action of quinacrine postulated by Grünhagen and Changeux¹¹.

The kinetic data reported here, obtained electrophysiologically, and those revealed by fluorescence^{2,3}, display resemblances when

using the same two agonists, in spite of differences in the techniques and preparations used. Since in the present experiments the slow process corresponds to a decrease in conductance, it is possible that the fluorescence increase seen when adding the agonist to microsac suspensions and which has a similar slow time course, does not monitor directly the activation of the receptor. Instead, we propose that quinacrine, like other local anaesthetics^{12,13}, blocks activated receptor-channel complexes. One interpretation of the voltage dependence of the quinacrine effect would thus be voltage sensitivity of the partitioning of cationic quinacrine between the external membrane surface and a blocking site within the channel¹⁴.

In the presence of quinacrine, the scheme describing endplate channel kinetics can be modified to

This scheme predicts two relaxation processes, as observed. It may be shown that if the two relaxation times are well separated, scheme 2 leads to the following expressions for the fast (τ_f) and slow (τ_s) relaxation time constants

$$1/\tau_f = \alpha + \beta + f + b$$

$$1/\tau_s = \frac{\beta f + \alpha b + \beta b}{\alpha + \beta + f + b}$$

In our experiments, the time constant of the control relaxation, $1/(\beta + \alpha)$, was very similar to that of the fast relaxation in the presence of quinacrine. This implies $(\beta + \alpha) \gg (f + b)$. With this condition the equation for τ_s simplifies to $1/\tau_s = f\beta/(\beta + \alpha) + b$.

Fig. 2 Slow quinacrine-induced relaxations during bath application of ACh to a voltage-clamped frog muscle endplate. ACh responses to fast agonist superfusion had times to peak less than 10 s . In each pair of traces, the upper trace shows the total clamp current recorded in the absence of ACh before, during and after rectangular hyperpolarising voltage jumps (from -60 mV to -140 mV , downward arrow, and back to -60 mV , upward arrow). Apart from the initial capacity transients, the passive currents are almost constant during the jumps. The lower traces in each pair show inward currents recorded during ACh action at 1-s time calibration, except for the beginning of each trace which shows the onset of the response to ACh perfusion (\blacktriangle) at a tenfold slower time base. The difference between the upper and lower traces in each block represents the ACh-induced endplate current. In the absence of quinacrine (*a*) the additional ACh-induced ($2 \mu\text{M}$) current flowing during the step is well maintained. In the presence of $1 \mu\text{M}$ quinacrine (*b*), the ACh current is not well maintained and shows a progressive decrease. This slow relaxation is clearly faster for $4 \mu\text{M}$ ACh than for $2 \mu\text{M}$. Note that the current at the holding potential evoked by $2 \mu\text{M}$ ACh is only slightly depressed by quinacrine. The fast relaxations in the absence and the presence of quinacrine cannot be resolved with total current recordings. In all bath application experiments using ACh, endplate cholinesterase was inactivated by a 90-min treatment with methyl, *O*-ethyl, 5-ethyldipropylamine phosphorothiolate at $0.5 \mu\text{M}$, followed by extensive washing. After the treatment, $25\text{--}30 \mu\text{M}$ carbachol was needed to match the response to $1 \mu\text{M}$ ACh; this was used as an indication of cholinesterase block. Cholinesterase was blocked so that the ACh concentration in the synaptic cleft would equal the bath concentration.

Fig. 3 Mean half-decay times (evaluated from semilog plots of relaxing currents) of slow quinacrine-induced relaxations at -140 mV membrane potential. The quinacrine concentration was $1 \mu\text{M}$, and the agonists were applied in the bath. The bars show ± 2 s.e.m., where this exceeds the symbol size. Experiments were from 13 *Rana pipiens* fibres. The agonist concentration (abscissa) is on a log scale. The data were plotted in this manner to facilitate comparison with Fig. 2 of ref. 2. ●, Acetylcholine; ○, carbachol.

Noise and relaxation experiments^{6,8} in the absence of quinacrine, which provide a direct measure of $(\beta + \alpha)$, show that β increases monotonically as the agonist concentration is increased, in a range comparable with that used here. Our model therefore predicts the monotonic decrease in τ , as the agonist concentration is increased (Fig. 3). The observation that for high agonist concentrations τ seems to reach a limiting value which is larger for carbachol than for ACh (Fig. 3 and Fig. 2 of ref. 3) suggests that carbachol cannot open all the endplate channels, even when acting at high concentration. In this model, the electrophysiological and fluorescence data are to be interpreted in slightly different terms, since the first would reflect the number of conducting channels remaining after quinacrine treatment, whereas intensity of fluorescence would directly monitor the amount of quinacrine bound to the receptor-channel complex.

This work was supported by grants from the CNRS, the DGRST and the ISERM. We thank Rhône-Poulenc for quinacrine.

Role of intracellular calcium in the transient outward current of calf Purkinje fibres

CALCIUM-activated currents are known in red blood cells¹, invertebrate neurones², vertebrate spinal motoneurones³ and skate electroreceptors⁴, and it has been suggested that intracellular calcium increases outward currents in cardiac muscle⁵⁻⁷. The possibility of calcium-activated currents in heart and other muscle^{8,9} is interesting because these cells have intracellular stores that release calcium. Some of the apparent complexity of membrane currents in muscle might be explained as a manifestation of excitation-contraction coupling. If internal calcium (Ca_i) en-

hanced a surface membrane conductance, one might expect a phasic current which reflected the increase and decrease in Ca_i during contraction. No such current has been identified in heart. We report evidence here that intracellular calcium controls the transient outward current which underlies the early repolarisation in cardiac Purkinje fibres^{10,11}. Thus the transient outward current is inhibited by blockers of calcium current, varies directly with the external calcium concentration and correlates with twitch amplitude in conditions which vary the amount of calcium released.

Short Purkinje fibre preparations from calf hearts were voltage-clamped by a conventional two-microelectrode method. In some experiments, contractile force was measured with a piezoelectric force transducer (Endevco 87102). Interference from the excitatory sodium current was prevented by blocking sodium channels with tetrodotoxin ($20 \mu\text{M}$) or inactivating them with a depolarised holding potential (~ -40 mV). The transient outward current is referred to as I_{qr} because the kinetic variables q and r have been used previously to describe its activation and inactivation^{11,12}.

In Fig. 1a, trace 1 shows a record of membrane current during a clamp depolarisation in the range of the action potential plateau. The outward transient current (I_{qr}) is dominant for the first 150 ms after the step depolarisation and obscures the slow inward calcium current (I_{Ca}). I_{Ca} turns on within a few ms after the depolarisation and then inactivates slowly¹³; the inactivation is largely responsible for the slow current change during the last 300 ms of the pulse. Efforts at quantitative analysis of I_{Ca} in Purkinje fibres have been hampered by such overlap with I_{qr} (refs 14, 15). We tried to determine I_{Ca} without interference from I_{qr} by a pharmacological dissection involving D600, a blocker of calcium currents¹⁶. But D600 inhibited the outward transient as well as I_{Ca} . In preparations showing large I_{qr} (Fig. 1a) the early current in the absence of D600 (1) was more outward than the current in its presence (2). Thus, the 'D600-sensitive current' (1-2, Fig. 1b) displayed a region of net outward current. We attribute the outward region to I_{qr} (shaded area) in combination with I_{Ca} . The inward spike in Fig. 1b is explained as a rapid activation of I_{Ca} preceding the activation of I_{qr} . Similar net current waveforms have been observed in crustacean muscle and have been analysed as a transient outward current superimposed on an inward calcium current^{9,17}.

The consistent reduction of I_{qr} obtained with D600 invalidates the use of this drug to determine I_{Ca} . But the results also suggested that I_{qr} is dependent on intracellular calcium. On this view, the reduction of I_{qr} would be accounted for as a natural consequence of the inhibition of calcium entry. We explored this hypothesis using procedures believed to modify calcium influx. Figure 1c shows that manganese ion, another widely-used blocker of calcium currents^{13,14}, resembles D600 in the ability to reduce I_{qr} . Figure 1d shows the effects of increasing the extracellular calcium concentration from 1.8 to 5.4 mM. Increased slow inward current is evident from the augmented early spike (arrows) and the downward displacement of current during the last 400 ms of the clamp pulse. The increase in external calcium (Ca_o) also produced a clear enhancement of I_{qr} , which was fully reversible (record not shown). An increase of Ca_o from 5.4 to 9.0 mM caused a further increase in I_{qr} .

Another approach to the possible involvement of intracellular calcium relied on contractile force to report changes in myoplasmic calcium activity. We took the amplitude of the twitch as a rough index of the calcium transient and compared it with the surge of I_{qr} during depolarising clamp pulses. The size of the calcium transient was varied by manipulating the previous history of membrane potential¹⁸. Figure 2a shows a typical voltage clamp protocol consisting of two identical depolarising pulses separated by a variable interval. The first pulse followed a 5-s quiescent period and produced a large transient outward current and a sizeable twitch contraction. The second pulse was applied after a 1.5-s repolarisation and evoked a smaller I_{qr} and smaller twitch. Earlier experiments of this type have shown that the level and duration of the repolarisation strongly influence the restitution of the second contraction¹⁸ and the recovery of the outward transient current¹¹. Here the question is whether these recovery processes share the same time and voltage dependence. Because this

Fig. 1 Effects of D600, manganese and calcium on the transient outward current (I_{qr}). *a*, Membrane current in the absence of drug (1) and after exposure to D600 (5×10^{-6} g ml $^{-1}$) for 30 min (2). The current records accompanied a rectangular membrane depolarisation from -40 to $+15$ mV for 500 ms (upper trace). Signals were recorded by a digital computer, sampling once every 3 ms. The smooth line was drawn by eye for clarity; preparation S22-1. *b*, 'D600-sensitive current', obtained by subtracting trace (2) from trace (1). Shaded area is estimate of I_{qr} , dashed line estimate of I_{qr2} . *c*, Membrane current in a control run and after exposure to 3 mM $MnCl_2$ for 9 min. The currents were evoked by a 500-ms clamp pulse from -38 to $+13$ mV. *d*, Membrane current in 1.8 mM Ca and 10 min after increasing the external calcium concentration to 5.4 mM. The arrows indicate the peak inward spike of current, an approximate measure of peak I_{qr} . Currents were in response to a 520-ms clamp pulse from -39 to $+13$ mV. *c* and *d*, Preparation R33-2. The composition of the Tyrode solution used in these experiments was 150 mM NaCl, 4 mM KCl, 10 mM Tris-HCl buffer, pH 7.4, 0.5 mM $MgCl_2$, 5.4 mM $CaCl_2$ and 5 mM glucose.

comparison depends on a fairly accurate determination of I_{qr} , we reduced interference from I_{si} by choosing preparations with relatively large I_{qr} , by using strong depolarisations to increase the driving force for outward current and by estimating I_{qr} with a graphical procedure (Fig. 2a) which made some allowance for I_{si} .

Figure 2b shows the influence of potential level on the recovery of the twitch and of I_{qr} . The results were obtained with a 1.5-s repolarisation interval and were normalised relative to the responses evoked by the first pulse. The contraction and the transient outward current show nearly identical dependence on membrane potential. Similar correspondence was observed in five out of six preparations. Figure 2c shows the recovery of the twitch and I_{qr} as the repolarisation interval increased progressively. Both signals show a similar time course. Temporal correlation was observed in six out of seven experiments of this kind, and was found at -70 mV as well as near -40 mV. The occasional lack of correlation might be explained by exceptionally severe contamination by I_{si} .

Although parallelism between I_{qr} and contractile force is clear and rather consistent, the agreement could be considered fortuitous. A purely coincidental explanation is not supported, however, by experiments in which the recovery time course was manipulated drastically. Cardiac glycosides and aglycones were useful for this because they modify the time course of contractile restitution as well as increasing the strength of contraction¹⁹. Figure 3 shows the influence of strophanthidin on the recovery of the twitch and of I_{qr} . In the absence of the drug, both transients showed a monotonic recovery with increasing repolarisation interval as in Fig. 2c. After exposure to 1 μ M strophanthidin, contractile restitution and recovery of I_{qr} both became oscillatory, with the same period and phase. The discrepancy in the height of the oscillatory peaks at 0.5 s could be explained if I_{qr} were more seriously underestimated at this time. Contamination from I_{si} may have been more severe at the peak because other experiments have shown that strophanthidin evokes a clear oscillation in the repriming of I_{si} (ref. 20). The inset in Fig. 3 illustrates another experiment using strophanthidin in which the time courses of I_{qr}

and I_{si} were particularly distinct. Clearly the amplitudes of I_{qr} , I_{si} and twitch force were each enhanced by a second pulse relative to their size during the first pulse.

These kinetic correlations between I_{qr} and twitch force, taken together with the actions of D600, manganese and extracellular calcium, strongly suggest that the transient outward current is controlled by intracellular calcium activity. The myoplasmic calcium could be supplied by release from intracellular stores or entry across the surface membrane. Contractile force provides a convenient and sensitive bioassay for the size of the intracellular calcium transient. This approach has drawbacks, however, since the peak of the twitch must lag behind the peak of calcium activity near the surface membrane because of diffusional, chemical and mechanical delays. It is possible that the waveform of I_{qr} is a more faithful representation of the time course of calcium activity than the externally measured force. Direct measurements of the calcium transient may soon be possible using optical indicators^{21,22}. Such experiments would provide another test for the present hypothesis and might determine whether intracellular calcium governs the time course of I_{qr} or if it merely acts as a trigger for a phasic conductance change.

Our results suggest that some of the time and voltage dependence of the transient outward current arises from the same mechanisms which underly activation and inactivation of contraction. The ionic nature of the outward current remains unsettled. Chloride was originally thought to carry I_{qr} because the outward transient was reduced by replacing chloride with larger anions^{10,11}. But Kenyon and Gibbons²³ have shown that the

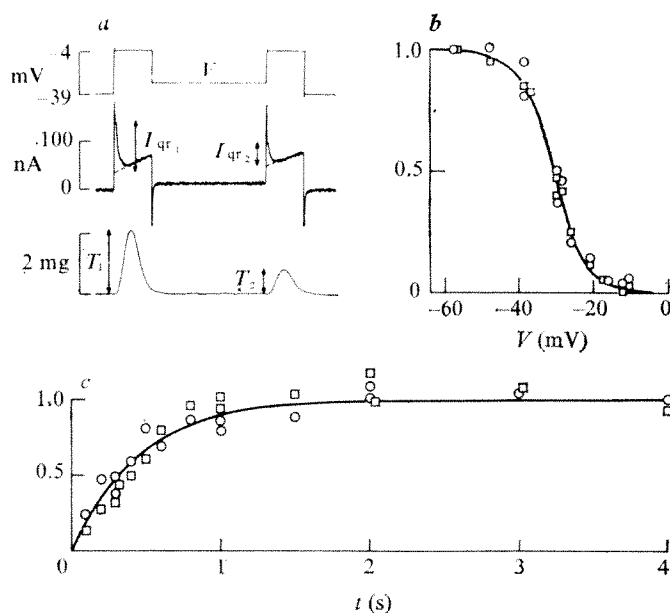

Fig. 2 *a*, Experimental records illustrating the protocol for obtaining the curves in (b) and (c). The traces (records from a Brush 440 pen recorder) show, from top to bottom, membrane voltage, membrane current and contractile force. The magnitude of I_{qr} was measured as the difference between the peak of the outward transient and a linear extrapolation of the late current to the time of peak I_{qr} (dashed line). This method will underestimate I_{qr} because it underestimates I_{si} . To correct for small progressive changes during the run, currents and tension during the second pulse were normalised by the response to the first pulse. *b*, Relationship between repriming potential (V) and the inactivation of I_{qr} (\square) and tension (\circ). The normalised I_{qr} and tension at a given repriming potential were divided by the normalised values for $V = -57$ mV to yield the inactivation curve. The continuous line was drawn according to $r = [1 + \exp((V + 31)/4)]^{-1}$, where r is a Hodgkin-Huxley type variable with values between 0 and 1. *c*, Comparison of the recovery from inactivation of I_{qr} and tension. Two depolarising voltage-clamp pulses were separated by repolarisation to the holding potential for a variable interval (t). Normalised I_{qr} and tension were plotted as a function of t . Symbols are as in (b). The continuous line is an exponential with a time constant of 450 ms. Voltage-clamp pulses in (a), (b) and (c) depolarised the membrane to -4 mV for 500 ms from a holding potential of -39 mV; preparation R25-2.

Fig. 3 Alteration of the repriming time courses of I_{qr} and tension by strophanthidin. In the absence of strophanthidin the repriming time courses of I_{qr} (\square) and tension (\circ) are very similar. The continuous line is an exponential with a time constant of 880 ms. The closed symbols were obtained 15 min after addition of $1 \mu\text{M}$ strophanthidin. Both repriming curves then show distinct oscillations. Repriming curves obtained with 500-ms clamp pulses from -40 mV to -10 mV . Preparation R27-2. The inset shows a chart recording from a less complete experiment in the presence of $1 \mu\text{M}$ strophanthidin; preparation R26-7.

substitute anions act by reducing extracellular calcium activity. Their results are consistent with the sensitivity of I_{qr} to deliberate variations in Ca_0 (Fig. 1d). Reports of calcium-activated potassium currents in other tissues raise the possibility that potassium ions help carry I_{qr} . Whatever the ionic basis of I_{qr} , its apparent dependence on intracellular calcium raises fundamental difficulties for analysis of the slow inward current in Purkinje fibres. A drug which interacts specifically with Ca_i channels will still have indirect effects on I_{qr} . Thus proper pharmacological dissection of Purkinje fibre plateau currents will require a method for selectively abolishing I_{qr} .

We thank Dr Peter McNaughton for suggesting that the transient outward current might be activated by intracellular calcium, and Drs K. Beam, T. Colatsky, W. R. Gibbons, J. L. Kenyon and R. Weingart and Mr W. Gilly for helpful discussions. This work was supported by a grant from the USPHS.

Voltage noise from hair cells during mechanical stimulation

THE generator potential of mechanoreceptor hair cells is thought to arise from a change in conductance of the receptor membrane¹⁻⁴. A mechanical force in the environment acts on hairs to cause the generator potential. The conductance change associated with the generator potential may be composed of many elementary conductances whose frequency or number vary with mechanical stimulation. From this hypothesis, one would expect to observe random fluctuations, or noise, associated with the generator potential. We report here the presence of such fluctuations in an invertebrate statocyst; the analysis of the fluctuations gives an estimate of the size of the underlying events associated with the generator potential during mechanical stimulation.

Hair cells of the invertebrate statocyst are presumably stimulated by statoconia. Increased interaction between statoconia and the cilia depolarises the hair cells; decreased interaction hyperpolarises them. The statoconia, however, are in constant motion. Random movement of these particles should cause a baseline noise¹⁻³. Figure 1 shows intracellular recordings from a hyperpolarised hair cell body of *Hermisenda crassicornis*. The cells were hyperpolarised by injecting current through the recording electrode to suppress spontaneous firing which normally occurs near rest at -55 mV . The preparation and the rotational method of physiological stimulation have been described elsewhere³. Hair cell somata were passively invaded by action potentials arising in the axon $80 \mu\text{m}$ from the soma, and received synaptic input at axonal branches $100 \mu\text{m}$ from the soma. The generator potential and voltage noise can be studied in the absence of impulses and synaptic interactions by cutting the distal axon (cut N⁵). Fig. 1a shows a depolarising response from a hair cell (cut N) in front of the force vector. In the absence of rotation, the variance in the voltage noise was $9.3 \times 10^{-8} \text{ V}^2$. A rotational velocity of 60 r.p.m.

Fig. 1 Intracellular recordings (0-313 Hz) from statocyst hair cells. The vertical bar represents 5 mV, the horizontal bar 5 s. *a*, A hair cell in front of the force vector with cut axon (cut N) to remove synaptic input. Rotation begins and ends at the arrows, and produces a maximum steady value of 0.8 g midway during the response. The holding potential is -100 mV . *b*, A hair cell with intact axon behind the force vector. Rotation begins at the arrow and produces a maximum steady value of 1.4 g. The holding potential is -80 mV .

for a cell located 19 cm from the centre of rotation, produced an average depolarisation of 5.5 mV and an increase in the variance to $29.3 \times 10^{-8} \text{ V}^2$. Figure 1b shows the opposite effect from a cell behind the force vector, the axon of which was left intact. The noise variance decreased from 12.0×10^{-8} to $2.1 \times 10^{-8} \text{ V}^2$ as a result of a rotational velocity of 75 r.p.m. The mean hyperpolarisation was 9 mV.

The variance of the microelectrode and amplifier noise, measured in the external bath, was less than 10^{-8} V^2 . The noise increased as the microtip entered the statocyst. Hyperpolarising the membrane with current further increased the noise (Fig. 2). Microelectrode noise measured in the external bath increased negligibly over the current range used. The voltage was held between -80 and -100 mV in the rotation experiments. In this range, the 'background noise', that is, membrane noise plus microelectrode and amplifier noise, varied between 2×10^{-8} and $10 \times 10^{-8} \text{ V}^2$. Changes were then studied as a function of the physiological stimulus.

Autocorrelation functions of the noise are shown in Fig. 3. At -80 mV and zero rotational velocity, the correlation function is approximated by a single exponential with time constant 74 ms. The 7-mV hyperpolarisation caused by rotation reduced the noise and increased the time constant to 168 ms. An increase in the speed of rotation, increased the hyperpolarisation to -9 mV and reduced the noise, with little further effect on the time constant. The noise level at -9 mV approached that caused by microelectrode and amplifier noise. A cell with similar background noise is shown for the depolarising response. Depolarisation to 16 mV increased the noise variance with no appreciable change in time constant. The smallest time constant observed for a depolarising response was 62 ms. The largest time constant observed for a hyperpolarising response was 178 ms.

The results of many experiments are summarised in Fig. 4 in which the change in noise variance is compared with the mean change in membrane potential, without regard to sign. Hyperpolarising and depolarising responses are presented for both intact hair cells and from hair cells with cut axons (cut N). The change in variance was roughly proportional to the change in the mean. A solid line, approximately determined by the data points, has a

Fig. 2 Intracellular recordings from statocyst hair cells, hyperpolarised from their resting value by current injection. The average resting potential is about -55 mV. One very noisy cell (upper dashed line) and one very quiet cell (lower dashed line) are shown. The solid line is drawn through pooled data from many cells.

Fig. 3 Autocorrelation functions of the noise in various conditions of rotation. The sample length was 27.31 s during steady rotation. The data were recorded on FM tape at 3.75 i.p.s. (0–625 Hz) after passing the signal through an RC high pass filter with a 2.2 s time constant. Processing was carried out off-line with a d.c.-coupled HP 3721A correlator after passing the signal through a RC high pass filter with an 8 s time constant. ●, Noise from a hair cell behind the force vector, at zero rotation and two levels of rotation which produce steady hyperpolarisations of 7 mV at 1.2 g and 9 mV at 1.4 g. ○, Depolarising response of 16 mV at 1.2 g from a cell with approximately the same zero rotation background noise. The lines represent exponentials with time constants 74 ms (upper) and 168 ms (lower). C is the value of the autocorrelation for relative time displacement τ .

slope of $12 \mu\text{V}$. This slope may be taken as the order of magnitude of the elementary voltage event associated with mechanotransduction. The dashed line in Fig. 4 represents the expected distortion of the variance-to-mean relationship produced by the summation of elementary increases in conductance. The soma membrane resistance with rest potential E is taken in parallel with the receptor membrane resistance with reversal potential e . The correction factor to $\Delta\sigma^2$ is f^4 and to ΔV is f , where $f = V_0/(V_0 - \Delta V)$ and $V_0 = e - E$ is the maximum possible ΔV . This analysis is similar to that applied to acetylcholine-induced noise at the neuromuscular junction⁶ and to changes in noise induced by light in bipolar cells and photoreceptors⁷.

Two experiments in Fig. 4 are from an abnormal *Hermisenda* statocyst which has only one or two statoconia instead of several hundred. Such a statocyst, which may be a mutant form, offers the possibility of studying the elementary statoconium-hair cell interaction more directly.

Are the changes in noise produced by rotation caused by the mechanotransduction or by changes in membrane potential? A change in membrane potential by current injection has the opposite effect to a change caused by physiological stimulation. For example, a hyperpolarisation caused by current increased the noise (Fig. 2), but a hyperpolarisation caused by rotation decreased the noise (Figs 1 and 4). The converse was true for the depolarising direction. We conclude that the changes in hair cell noise analysed here are caused by mechanotransduction.

Since the change in variance is roughly proportional to the mean, the potential changes due to mechanotransduction can be considered as the sum of random events according to a simple shot model. The model is discussed fully by Katz and Miledi⁶. The basic relationship for a random sum of exponential events, each of height a is: $a = 2\Delta\sigma^2/\Delta V = 24 \mu\text{V}$. The spread of data in Fig. 4 is

due to a variation in the time constant with different levels of rotation (Fig. 3) and to the subtraction procedure.

The largest time constant previously observed by the displacement of voltage with current pulses was 45 ms¹. The relaxation times shown in Fig. 3 may be caused by transduction or by an induced change in input resistance. The input resistance could be expected to decrease for the depolarising response and increase for the hyperpolarising response, although we have no direct evidence that this occurs. In either case, a random event with a single relaxation time for a particular stimulus describes the effect shown in Fig. 4. The input resistance of the hair cells at rest is 80–100 MΩ. If the amplitude of an individual event is taken as 24 μV, one calculates an elementary current of approximately 0.3 pA for each event. It was shown recently that hair cell generator potentials and voltage noise are dependent equally on sensory stimuli, membrane potential, external sodium concentration, and treatment with the anaesthetic, chloral hydrate (D.L.A., Y. Grossman and E. Heldmann, unpublished).

These observations support the hypothesis that the voltage noise reported here involves the same mechanism that underlies the generator potential. The generator potential arises from a conductance increase with a reversal potential of about 30 mV positive with respect to rest¹. From an average holding potential of -90 mV, we assume a driving force of 60 mV. The elementary conductance change associated with each event is therefore about 5 pS. This is the order of conductance found for individual ionic channels⁸. Although there is considerable uncertainty in the reversal potential, even if 30 mV positive with respect to zero is assumed, the estimate for the elementary conductance change is merely halved.

Our observations show that the changes in hair cell membrane potential do not account for the changes in noise produced by a physiological stimulus. The changes in noise produced by rotation are primarily caused by the transduction process itself, indicating a common origin for voltage noise caused by rotation and by the hair cell generator potential. We conclude that the generator potential is the result of a random sum of elementary events which have an average effect (the generator potential) and a fluctuating component (the voltage noise). Local potential phenomenon previously reported by Alkon³ do not occur at the holding potentials used here, nor do they occur in hair cells with cut axons. Thus, such effects could not contribute to the noise studied here.

The number of hairs interacting with one statoconium is

Fig. 4 Change in noise variance ($\Delta\sigma^2$) against the change in mean membrane potential (ΔV) at different levels of rotation. \times , Hair cells with cut axons (cut N) showing a depolarising response. Hair cells with intact axons showing a depolarising (○) or hyperpolarising (●) response. (●) From an abnormal statocyst with one or two statoconia. Eleven different cells are represented in this figure. The solid line represents $\Delta\sigma^2/\Delta V = 12 \mu V$. The dashed curve represents the expected nonlinear effect of increased conductance on the depolarising response assuming a maximum ΔV of 90 mV. The variance was taken as the first point of autocorrelation functions calculated from 13.65 or 27.31 s of data.

estimated to be between 1 and 20, based on scanning electron micrographs (D.L.A., Y. Grossman and E. Heldmann, unpublished). Discrete depolarising waves observed in the voltage noise near rest³ probably reflect the interaction of a statoconium with one or more cilia. These depolarising waves range from 1–10 mV. If the lower limit of 1 mV is taken to approximate the interaction of a single statoconium with a single hair, 40 elementary events, each causing a 5-pS increase of conductance, would be necessary. Noise analysis offers the possibility of relating molecular membrane phenomena, which are not directly observable, to the mechanism of the generator potential of a sensory receptor.

Stimulation of the sympathetic nervous system during sucrose feeding

THE activity of the sympathetic nervous system in the rat is markedly reduced by 2 d of fasting, and this suppression is reversed by feeding¹. Studies of urinary catecholamine excretion in fasting rats have corroborated these findings and in addition have shown that urinary adrenaline and noradrenaline (NA) excretion actually exceed baseline levels on the second and third days of refeeding². Since dietary intake in these previously fasted animals was greater than baseline during the refeeding period, the possibility arose that overfeeding might be associated with increased sympathetic activity and led to the present investigation. Work by others has provided evidence that supplementation of a standard rat chow diet with sucrose-containing drinking solutions increases total caloric intake of the rat by approximately 20%³. Thus the experimental design for voluntary overfeeding in the rat is based on the addition of sucrose-containing drinking solutions to the animals' *ad libitum* access to rat chow and water during the experimental period. In this report we describe increased sympathetic activity in the hearts of overfed animals after 3 d of sucrose supplementation. Such an increase in sympathetic activity may contribute to the enhanced thermogenesis associated with overfeeding.

The use of NA turnover techniques in assessing the functional state of the unperturbed sympathetic nervous system permits the estimation of organ-specific sympathetic activity in each sympathetically innervated organ. NA, the sympathetic neurotransmitter, is synthesised and stored within the sympathetic nerve endings and is released in response to neural impulses. An active transport mechanism in the neuronal membrane recaptures a major fraction of the released NA. As the activities of both NA biosynthesis and NA re-uptake are coupled to the level of impulse traffic, the endogenous level of NA within the nerve terminals in a particular organ is relatively constant despite wide fluctuations in sympathetic activity. The kinetic measurements of NA turnover used here use these neuronal processes of NA biosynthesis and active transport to quantitate changes in the level of sympathetic activity in experimental conditions. The ³H-NA turnover

technique involves the intravenous (i.v.) administration of tracer doses of ^3H -NA. After uptake of the label into the sympathetic nerve endings and equilibration with intraneuronal stores, the rate of disappearance of the tracer provides an indication of sympathetic activity within a particular organ. Previous work with this technique has established its usefulness as a measure of sympathetic activity in various physiological and pathophysiological conditions⁴⁻⁶. A second method of assessing NA turnover involves inhibition of NA biosynthesis with α -methyl-*P*-tyrosine (α MPT), an inhibitor of tyrosine hydroxylase, the rate-limiting step in NA biosynthesis. In the presence of such inhibition endogenous NA levels cannot be maintained and the rate of fall of endogenous NA reflects NA turnover. Intraneuronal metabolism of NA contributes to a limited extent to these measurements of NA turnover, but is not altered by the experimental conditions described here.

Female Sprague-Dawley rats (150–200 g) were used in these experiments. These animals were allowed free access to Purina rat chow and water except as noted in the experimental protocols. The effect of 3 d of sucrose feeding on NA turnover as measured by the rate of disappearance of ^3H -NA is shown in Fig. 1. In this experiment control (normal diet) and sucrose-fed animals received an i.v.

Fig. 1 ^3H -NA turnover in rat heart in control and sucrose-fed animals. Female Sprague-Dawley rats (150–200 g) were divided into two groups 3 d before the start of the NA turnover experiment. Control animals (○) remained on their *ad libitum* diet of rat chow and water; sucrose-fed animals (●) were provided access to an 8% sucrose solution in addition to their rat chow and water. At the beginning of the turnover, each animal received an i.v. injection of ^3H -NA (250 μCi per kg body weight; specific activity 24.4 Ci mmol⁻¹; New England Nuclear) by tail vein. At 2, 6, 12 and 24 h after injection, five to seven rats from each group were killed, their hearts removed and quickly frozen on dry ice. The organs were stored at -20°C until analysed within 2–3 d. After the organs were homogenised in ice-cold 0.4 M perchloric acid, NA was isolated chromatographically with alumina and the eluates analysed for ^3H -NA and NA content, as previously described⁶. Values were corrected for recovery (80–90%) as determined in each experiment. Specific activity of cardiac NA was determined for each time point, expressed as mean \pm s.e.m. The line representing the decline in specific activity with time was calculated by the method of least squares. For both control and sucrose-fed groups, the significance of each slope is $P < 0.001$. For the control group the slope or fractional turnover rate is $4.80 \pm 0.16\%$ per h with a NA turnover rate of 21.4 ± 1.9 ng NA per heart per h (95% confidence interval). For the sucrose-fed group the fractional turnover rate is $8.49 \pm 0.13\%$ per h and the NA turnover rate 30.6 ± 2.3 ng NA per heart per h (95% confidence interval). The slopes are significantly different at the $P < 0.001$ level using the Student's *t* test. Sucrose intake averaged 5.5 g per rat per d for the experiment. For control, $t_1 = 14.5 \pm 0.5$ h; for sucrose-fed rats, $t_1 = 8.2 \pm 0.1$ h.

Fig. 2 Effect of inhibition of NA biosynthesis on endogenous NA levels in rat heart from control (normal diet), fasted and sucrose-fed animals. Animals were prepared as described in Fig. 1, except that in this experiment, a single group of animals was fasted for 48 h before the start of the experiment. Animals were injected i.p. with the methyl ester of α MPT (Sigma) dissolved in saline, 250 mg per kg at zero time and 125 mg per kg at 3.5 h; controls received the diluent alone in two injections. Animals were killed at 7 h, and the endogenous NA levels in heart determined. Open bars represent the saline-treated animals, the shaded bars the α MPT-treated animals, and the striped bar a single group of α MPT-treated animals that was placed in cages in a cold (4°C) room during the course of the experiment. Each group contained eight or nine animals. * Represents $P < 0.005$ and ** represents $P < 0.001$, when compared with the corresponding diluent control. The endogenous NA content in α MPT-treated animals is significantly less ($P < 0.02$) in those fed sucrose compared with those maintained on the control diet. Sucrose intake averaged 6.2 g per rat per d during the experiment.

injection of ^3H -NA at t_0 . At 2, 6, 12 and 24 h after injection, 5–7 rats from each group were killed and their hearts analysed for ^3H -NA and endogenous NA. As shown in the semi-logarithmic plot of cardiac NA specific activity against time (Fig. 1), sucrose feeding was associated with a highly significant ($P < 0.001$) decrease in the calculated half-time of disappearance (t_1), from 14.5 ± 0.5 h in the control group to 8.2 ± 0.1 h in the sucrose-fed group. (Similar differences were observed when cardiac ^3H -NA content was plotted against time.) The fractional NA turnover rate was increased significantly ($P < 0.001$) during sucrose feeding (from $4.80 \pm 0.16\%$ per h in the control group to $8.49 \pm 0.13\%$ per h in the sucrose-fed group). Endogenous levels of cardiac NA decreased significantly ($P < 0.02$) in the sucrose-fed rats compared with the control animals (360 ± 21.7 and 446 ± 25.4 ng NA per heart, respectively). NA turnover rate, calculated as the product of the fractional turnover rate and the endogenous level, was increased in the hearts of sucrose-fed animals (21.4 ± 1.9 and 30.6 ± 2.3 ng NA per heart per h for the 95% confidence intervals in control and sucrose-fed animals, respectively). Sucrose feeding for 3 d, therefore, is associated with increased ^3H -NA turnover.

The effect of inhibition of NA biosynthesis on endogenous levels of NA in hearts of control (normal diet), fasted and sucrose-fed animals is shown in Fig. 2. With both control and sucrose-fed groups significantly ($P < 0.005$ and $P < 0.001$, respectively) decreases in the NA content of rat heart followed 7 h of inhibition of NA biosynthesis; cardiac NA levels were significantly ($P < 0.02$) less in the α MPT-treated control animals, and were similar to the NA levels observed in control animals exposed to cold (4°C). Fasted animals exhibited no change in cardiac NA content after α MPT treatment as previously reported. Thus, two independent methods for assessing NA turnover demonstrate increased NA turnover during sucrose feeding.

Ganglionic blockade interrupts central sympathetic

outflow and as a result decreases peripheral sympathetic activity. The effect of such blockade on endogenous NA and on the residual ^3H -NA remaining in the hearts of control and sucrose-fed animals 10 h after administration of label is shown in Fig. 3. In this experiment chlorisondamine (5 mg per kg, body weight intraperitoneally), a long-acting ganglionic blocking agent, was administered at 5 min, and again at 5 h, after injection of tracer NA into control and sucrose-fed animals. The animals were killed 10 h after the start of the experiment. In the control animals the residual ^3H -NA was 41% ($P < 0.025$) and the endogenous NA 14% (not significant) greater in the group treated with ganglionic blockade compared with the group given saline. In the sucrose-fed animals ganglionic blockade increased residual ^3H -NA 109% ($P < 0.001$) and endogenous NA 23% (not significant). The hearts of sucrose-fed animals without ganglionic blockade contained less ^3H -NA and endogenous NA than did those of the control animals ($P < 0.02$ and $P < 0.05$, respectively) consistent with increased NA turnover while no differences in either residual ^3H -NA or endogenous NA were observed in the hearts of sucrose-fed and control animals with ganglionic blockade. This abolition of differences in cardiac ^3H -NA content between control and experimental groups with ganglionic blockade indicates that increased central sympathetic outflow underlies the accelerated NA turnover observed in the hearts of sucrose-fed animals.

This report, in addition to our previous finding that sympathetic activity is suppressed during fasting, suggests that central sympathetic outflow is influenced by the nutritional state of the animal. The nutritional signal to the central nervous system that leads to the observed alterations in sympathetic activity is unknown. Nutritional modification of central sympathetic outflow may have several important implications. As catecholamines are considered to be the principal mediators of cold-induced thermogenesis^{7,8} and as the mechanisms of thermogenesis are presumed to be similar during cold exposure and with

overfeeding⁹, dietary-induced changes in sympathetic activity may have a central role in nutritionally-determined thermogenesis¹⁰. The physiological importance for cardiovascular disease of the increased sympathetic activity in heart associated with over-feeding is unknown, but dietary alterations in sympathetic activity may be a possible link between the increase in calorie and/or sucrose consumption and the rise in cardiovascular disease observed in Western countries¹¹.

Occurrence of a new class of tetrahydroisoquinoline alkaloids in L-dopa-treated parkinsonian patients

THE chemotherapeutic administration of massive doses of L-3,4-dihydroxyphenylalanine (L-dopa) with or without peripheral decarboxylase inhibitors to parkinsonian patients can lead to aberrant metabolism which may influence the efficacy of the regime. It is generally agreed that the transformations can include spontaneous chemical reactions facilitated by the inherent reactivity of the catechol nucleus. For example, Sandler *et al.*¹ reported the excretion of tetrahydroisoquinoline alkaloids (TIQs), tetrahydropapaveroline (norlaudanoline) and salsolinol by parkinsonian patients who had consumed large doses of L-dopa and ethanol. The same two TIQs have been detected in brain and urine of mammals administered alcohol and a second compound—for example, L-dopa or pyrogallol; and it has been proposed that these Pictet-Spengler condensation products (of dopamine and dopaldehyde or acetaldehyde, respectively) may be responsible for addiction in alcoholism²⁻³. We report here the occurrence of a new class of TIQs, norlaudanolinecarboxylic acids (NLCAs), in the urine of parkinsonian patients on L-dopa with or without carbidopa. Comparative studies with rats on a similar regimen reveal the presence of NLCAs in brain as well as in urine.

NLCAs arise by Pictet-Spengler condensation of phenylpyruvic acids and dopamine (Fig. 1). The parent compound, NLCA, derived from the transamination and decarboxylation products of L-dopa, has been previously characterised and implicated in *Papaver* alkaloid biosynthesis in higher plants^{6,7}. Norcoclaurinecarboxylic acid (NCCA), 3'-O-methylnorlaudanolinecarboxylic acid (MNLCA), and 3',4'-desoxynorlaudanolinecarboxylic acid were synthesised from dopamine and *p*-hydroxyphenylpyruvate, 3-methoxy-4-hydroxyphenylpyruvate and phenylpyruvate respectively, as described for NLCA (ref. 6). Their ultraviolet, nuclear magnetic resonance, infrared and mass spectra were consistent with assigned structures. NLCAs were detected in urine by mass fragmentography on an LKB-9000 gas-liquid chromatograph mass spectrometer. The presence of a carboxyl group dictated a two-step derivatisation of the alkaloids, entailing esterification with

Fig. 3 Effect of ganglionic blockade on *a*, cardiac ^3H -NA and *b*, cardiac endogenous NA in control (normal diet) and sucrose-fed rats. Animals were prepared for this experiment by 3 d of sucrose feeding as in Fig. 1: 5 min and 5 h after the i.v. injection of the ^3H -NA (200 μCi per kg) chlorisondamine (5 mg per kg; Ecolid, Ciba), a ganglionic blocking agent, was administered intraperitoneally. Control animals received similar i.p. injections of diluent. Animals were killed 10 h after injection of the ^3H -NA. Open bars represent saline-treated animals; shaded bars the chlorisondamine groups. Each group contained eight or nine rats. The percentage shown over the bar is the increase over the group without ganglionic blockade. ** Represents $P < 0.025$ and *** $P < 0.001$ compared with control without ganglionic blockade. ^3H -NA and endogenous NA content are significantly lower ($P < 0.02$ and $P < 0.05$, respectively) in the hearts of diluent-treated, sucrose-fed animals compared with diluent-treated, control animals, while no significant differences obtain in control and sucrose-fed animals in the presence of ganglionic blockade. Sucrose intake averaged 8.8 g per rat per d.

pentafluoropropanol followed by acylation of the phenolic and amino groups with heptafluorobutyric anhydride by a modification of a procedure for simple catechol carboxylic acids⁸.

In early experiments single ion monitoring was used and the instrument was focused on the debenzylated fragment (m/e 928), which represented the base peak in mass spectra of all NLCA derivatives. Subsequently the mass spectrometer was interfaced with a Logos Spectrotek computer system which allowed repetitive scanning of the gas-liquid chromatography effluent and data storage. Typical fragment ion current chromatograms generated by the computer from runs with standards and a urine sample are shown in Fig. 2.

The alkaloids were detected by monitoring both the base peak at m/e 928 and benzyl fragment ions (m/e 303 for NCCA, m/e 333 for MNLCA, m/e 91 for 3', 4'-desoxy NLCA). The benzyl fragment ion of NLCA had too low an intensity for routine detection.

With these semi-quantitative techniques the urine of normal subjects (controls) and parkinsonian patients on L-dopa, L-dopa-carbidopa (10:1, Sinemet) or no chemotherapy, were analysed (Table 1). Low but reproducible levels of MNLCA were detectable in urine of L-dopa- and Sinemet-treated parkinsonian patients. NLCA and MNLCA values were obtained for controls and non-treated patients but these were too close to minimal levels of detection to be conclusive. This was also the case for NLCA in treated parkinsonian subjects.

Comparative studies have been carried out with 250 g male Sprague-Dawley rats maintained on 2.5 mg L-dopa or 1.1 mg L-dopa-carbidopa (10:1, Sinemet) per ml drinking water (*ad libitum*) for 1 week. The animals consumed 5–30 mg L-dopa per day and excreted NLCA and MNLCA at a rate of 0.05–48 μ g per 24 h. Brain levels of MNLCA for L-dopa-treated rats averaged 202 ng per g tissue, a value confirmed independently by ion pair reversed phase high-pressure liquid chromatography.

After incubations in physiological conditions (0.2 M phosphate buffer, pH 6.0, at 37 °C for 30 min), 3,4-dihydroxyphenylpyruvate (14 mM) and dopamine (18 mM) reacted to produce 2–3% NLCA in the presence of cell-free homogenates of rat brain tissue. The fact that comparable yields were realised in the absence of brain tissue extracts or with boiled homogenates proved that the condensation was not enzyme dependent. Furthermore, enzymes such as monoamine oxidase, which were demonstrated to be active in these homogenates, did not interfere with the Pictet-Spengler condensation.

In vivo synthesis of MNLCA was demonstrated with rats fed Sinemet for 1 week as described above. The animals were injected intraperitoneally with 0.5 mCi 2,3-³H-L-dopa and killed 1.5–2 h later. Carrier MNLCA (10 mg) was added to *n*-butyl alcohol-ethyl acetate (3:2) extracts of brain

Fig. 1 Pictet-Spengler condensation of dopamine and phenylpyruvates.

Fig. 2 Fragment ion current chromatograms of derivatised NLCA standards and urine samples by computerised gas-liquid chromatography and mass spectroscopy. Solid NaCl was added to 5 ml urine until saturation, and the solution was extracted with 4 \times 5 ml *n*-butyl alcohol-ethyl acetate (3:2). The combined organic phase was evaporated to dryness and taken up in a buffer solution of 0.2 M sodium acetate, pH 8.6, 0.1% EDTA and 1% sodium metabisulphite. Acid-washed alumina (500 mg) was added to this solution and the pH adjusted to 8.6 \pm 0.1. This mixture was added to a column of acid-washed alumina (750 mg) pre-equilibrated with buffer and the column was washed with 4 volumes of 1 M HCl. The eluate was saturated with solid NaCl and extracted with 4 \times 0.75 ml *n*-butyl alcohol-ethyl acetate (3:2). The combined organic phase was taken to dryness. Recovery of NLCAs in this process ranged from 50–80%. Pre-incubation of urine with glucosylase did not increase yields appreciably. Derivatisation was accomplished by adding to the dry sample 100 μ l 1-H,1-H-pentafluoropropanol-1 (PCR) and 200 μ l heptafluorobutyric anhydride (Aldrich) and heating at 90 °C for 1–3 h. The sample was then taken to dryness with a stream of dry nitrogen gas; 100 μ l heptafluorobutyric anhydride was added and the sample was heated at 90 °C for 15 min. After removal of excess reagent with nitrogen, the sample was taken up in 200 μ l of either anhydrous ethyl acetate or acetonitrile containing 10% (v/v) heptafluorobutyric anhydride. The sample (1–5 μ l) was injected on to a 6-feet silanised glass column (4 mm internal diameter) packed with 3% OV-17 on Gas-Chrom Q (100–120 mesh) in the following conditions: carrier gas, nitrogen; flow rate 30 ml min⁻¹; ion source temperature 290 °C; flash heater 230 °C; column temperature 160 °C; accelerating voltage 2.5 kV; ionising energy 30 or 70 eV; trap current 60 or 120 μ A. Upscans were 4 s and rescans took 1.8 s. The urine sample shown here was obtained from a parkinsonian patient on 1.5 g L-dopa per day. a, Standards; b, urine analysis.

Table 1 Urinary levels of NLCA in controls and parkinsonian patients

Drug regimen	NLCA (μg per 24 h)	MNLCA (μg per 24 h)	Dopamine (mg per 24 h)
Controls (3)	0	8.4 [0-39]	1.19 \pm 0.27
Sinemet (6)	1.1 [0-7.1]	40.0 [10.9-149.5]	15.2 \pm 3.3
L-Dopa (3)	2.2 [0.6-3.8]	127.7 [55.5-235.9]	204 \pm 66
None (2)	0	3.3 [1.3-5.3]	0.66 \pm 0.18

Urine samples (24 h) were collected from normal subjects (controls) and parkinsonian patients on Sinemet (0.3-0.8 g L-dopa and 30-80 mg carbidopa per day), L-dopa (1.5-4.0 g per day), or no chemotherapy. Urine was stored immediately at -20°C after addition of either 5 ml 6 M HCl or 10 g sodium metabisulphite. TIQ levels did not change with time in these conditions. The values in parentheses indicate the number of subjects used. TIQ values were obtained by mass fragmentography and for MNLCA represent the average of at least two determinations for each individual, with the range of values given in brackets. Dopamine values (mean \pm s.e.m.) were obtained by paired ion high pressure liquid chromatography on a reversed phase column (unpublished results). Levels of 3,4-dihydroxyphenylpyruvate and 3-methoxy-4-hydroxyphenylpyruvate were below the limits of detection of the latter method ($< 0.1 \mu\text{g}$ per ml urine).

and intestinal tissues; it was then recrystallised to constant specific activity⁸. Final specific activities of MNLCA from gut of four different rats were 536-3,342 d.p.m. per mg ($6.5 \times 10^{-4}\%$ incorporation), whereas MNLCA from brain tissue of two rats gave constant specific activities of 231 and 599 d.p.m. per mg ($2.1 \times 10^{-4}\%$ incorporation). Labelled MNLCA was not found in rat liver or kidney in these experiments.

To determine whether endogenous levels of L-dopa metabolites had diluted the tracer, thereby depressing incorporation rates, an experiment was carried out in which an untreated rat was injected intraperitoneally first with carbidopa (1 mg per kg) and 0.5 h later, with 0.5 mCi $2,3\text{-}^3\text{H}$ -L-dopa. The percentage incorporation (1.64×10^{-4}) of L-dopa into MNLCA in the gut of this rat did not differ appreciably from the *in vivo* tracer data obtained with Sinemet-treated rats. Rates of *in vivo* conversion of L-dopa to MNLCA were more consistent with a spontaneous chemical reaction than with an enzyme-catalysed reaction. MNLCA formation in gut, in contrast to liver and kidney, reflects the intensive metabolism of L-dopa in the intestine of the rat⁹. Despite the low rates of incorporation, brain levels of MNLCA suggest accumulation can occur, possibly analogous to non-enzymatic melanin formation and deposition in brain.

To determine whether NLCA can interfere with normal catechol metabolism, they were included in enzyme incubations. Neither 0.1 mM NLCA nor MNLCA had an effect on V_{max} or the apparent K_m of tyrosine aminotransferase (29 nmol per min per mg protein and 2.1 mM, respectively) or L-aromatic amino acid decarboxylase (43 nmol per min per mg protein and 0.60 mM, respectively) in crude rat liver cytosolic fractions. Low concentrations of NLCA also did not seem to affect hepatic catecholamine catabolic enzymes *in vivo*. If 0.2 mg NLCA, MNLCA or 3',4'-desoxyNLCA and $7\text{-}^3\text{H}$ -L-noradrenaline (2 μCi , 0.2 nmol) were injected simultaneously into the tail vein of male Swiss albino mice (17-20 g) the percentage ^3H label in hepatic normetanephrine and vanillyl glycol was not appreciably different from control experiments in which noradrenaline was injected alone. Specific radioactivities were determined after fractionation by high-pressure liquid chromatography.

The question has been raised as to whether the efficacy of L-dopa chemotherapy in parkinsonism can be attributable to dopamine replacement alone. TIQs have been proposed as possible therapeutic agents¹⁰, whereas some investigators^{11,12} have postulated that they may cause side-effects such as the 'on-off' phenomena observed

clinically in L-dopa chemotherapy. These hypotheses imply interaction of TIQs with catecholaminergic receptors, and evidence exists for transmitter-like behaviour of simple aldehyde-derived TIQs⁴. Thus, the occurrence of NLCA in human urine and rat urine and brain demonstrated here, provides a basis for further investigation of theories concerning the role of TIQs in parkinsonian chemotherapy.

γ Endorphin, α endorphin and Met-enkephalin are formed extracellularly from lipotropin C fragment

A SERIES of peptides derived from lipotropin has been reported to possess morphinomimetic properties. The C fragment (or β endorphin, residues 61-91) was isolated from pituitary^{1,2} and shown to be present in brain³, the C' fragment (61-87) occurs in pituitary¹, γ endorphin (61-77) and α endorphin (61-76) were obtained after acid extraction of tissue of hypothalamic and pituitary origin⁴, and Met-enkephalin (61-65) was found in extracts of brain^{5,6}. Examination of the ability of these peptides to displace specifically bound ^3H -naloxone from brain opiate receptors showed that C fragment was much more potent than the shorter peptides⁷ and investigation of the antinociceptive properties showed that C fragment alone produces profound and long-lasting analgesia⁸⁻¹¹. In addition, various other central activities are exhibited by C fragment¹²⁻¹⁴. We report here that C fragment can be degraded by membrane bound enzymes from rat brain to form the smaller opiate-like peptides.

The use of iodine-labelled peptide, with the radiolabel on the NH_2 -terminal tyrosine, ensured that the substrates could be studied at near physiological concentration and products containing the NH_2 -terminal region of C fragment were readily identified. Membranes from rat brain were prepared by extensive washing of the synaptosomal fraction (P_2) described by Whittaker *et al.*¹⁵. Incubations of [^{125}I]C-fragment (100,000 d.p.m.; 2 Ci mmol⁻¹) with membrane preparations (0.42 mg per ml) were performed in 10^{-3} M bacitracin for 16 h at 37°C in 1 ml of 0.05 M sodium chloride-0.1 M sodium phosphate at pH 7.4 or 0.1 M ammonium acetate at pH 5 and the suspensions were gently agitated. The products were resolved by gel filtration on Sephadex G-50 in 50% (v/v) acetic acid and chromatography on thin layers of cellulose MN400 with *n*-butanol-pyridine-acetic acid-water (15 : 10 : 3 : 12; v/v) or *n*-propanol-0.2 M ammonium hydroxide (3 : 1; v/v). Shorter peptides (LPH 61-67 or 61-68, 0.34 mM) were incubated with membranes in similar conditions for 1 h and the mixtures were fractionated by

Fig. 1 Gel filtration of the products of digestion of [125 I] C fragment with membrane-bound proteases from brain. Brain digests were prepared as described in the text. After addition of an equal volume of acetic acid, membranes were removed by centrifugation. The supernatant was concentrated *in vacuo* at 40 °C and gel filtration carried out on a 150 \times 1 cm Sephadex G-50 column in 50% (v/v) acetic acid; fractions (1.8 ml), flow rate of 6 ml h $^{-1}$. ●, Elution profile obtained after digestion at pH 7.4; ○, profile obtained at pH 5.0. Fractions pooled as indicated by the horizontal bars were evaporated to small volume and portions were subjected to thin layer chromatography together with reference peptides¹⁶. Fractions 28–33 contained residual C fragment, fractions 38–46 contained only γ endorphin (pH 7.4) or α endorphin together with 61–73 (pH 5), fractions 52–60 contained Met-enkephalin (pH 7.4) and 61–68 (pH 5) and fractions 64–73 contained tyrosine.

gel filtration on Sephadex G-25 in 50% acetic acid and preparative electrophoresis on paper. Identification of the reaction products was by amino acid analysis.

At pH 7.4 in the presence of bacitracin (Fig. 1) the main product formed from C fragment was γ endorphin (61–77); there was in addition a small amount of Met-enkephalin (61–65). At lower pH values, C fragment was converted rapidly and in high yield to α endorphin (61–76) and Met-enkephalin. The heptapeptide (61–67) generated Met-enkephalin and the dipeptide Thr-Ser readily even at neutral pH.

The endopeptidase activity, assayed by release of Met-enkephalin from the heptapeptide 61–67, was associated with membranes but the enzyme could be detected in intact as well as lysed synaptosomal preparations. Moreover, the enzyme did not co-purify with the membrane components carrying the opiate receptors. When extensively washed synaptosomes were lysed and the membrane fragments resolved on sucrose density gradients, the membranes with affinity for 3 H-dihydromorphine were concentrated in the central fractions of the gradient whereas the endopeptidase activity was distributed uniformly. The results indicate that the endopeptidase is not an intrinsic component of the opiate receptor complex.

On incubation with striatal slices, [125 I]C-fragment underwent slow degradation with a half life of 3.2 h whereas the half life of [125 I] γ endorphin was 1.1 h. Residual peptide was determined by chromatography of the medium on Sephadex G-50 (Fig. 2). With C-fragment no stabilisation occurred on addition of bacitracin but the aminopeptidase inhibitor had a pronounced effect on the degradation of γ endorphin. The results show that the degradation of C fragment in striatum is not initiated by the attack of an aminopeptidase. The first step, as with the proteolysis catalysed by brain membranes, must involve attack by an endopeptidase.

The specificity of the endopeptidase was determined by examination of the soluble fraction of the incubation mixture. Gel filtration on Sephadex G-50 showed that the disappearance of C fragment was accompanied by the appearance of peptide fractions of lower molecular weight which retained the NH $_2$ -

terminal region of C fragment (Peaks I and II, Fig. 2). The formation of fraction I was markedly enhanced in the presence of bacitracin and ion-exchange chromatography showed that the major product was γ endorphin (Fig. 3). While the yield of γ endorphin was increased by bacitracin, continued incubation with the aminopeptidase inhibitor led to the formation of α endorphin in addition to γ endorphin. Thus, although C fragment is resistant to the action of aminopeptidases¹⁶ and carboxypeptidases¹⁷, γ endorphin is more susceptible to both enzymes.

A small percentage of short peptides retaining the NH $_2$ -terminal section of C fragment was observed during the gel filtration on Sephadex G-50 (Peak II, Fig. 2). Resolution of this fraction showed that the major component was Met-enkephalin and there was also some hexa- or heptapeptide (Fig. 4). Even though the small peptides are susceptible to degradation by exopeptidases, their formation was not greatly enhanced by the addition of bacitracin. It seems that the endopeptidase cleavage of γ and α endorphin proceeds only with difficulty.

The degradation of C fragment by membrane-bound enzymes and by striatal slices takes place in discrete stages, forming γ endorphin, α endorphin and Met-enkephalin. The accumulation of these peptides is strongly favoured by the presence of bacitracin or by acid pH, conditions which prevent the loss of the NH $_2$ -terminal tyrosine.

The degradation seems to be mediated by extracellular enzymes and does not involve a tissue uptake system because

Fig. 2 Gel filtration of [125 I] C fragment incubated with striatal slices. Coronal slices (about 200 mg wet weight) through the corpus striatum were prepared by section of fresh rat brains 3.5 mm and 2.5 mm rostral to the anterior part of the optic chiasma. The slices were pre-incubated (45 min, 37 °C) in 3 ml of saline (NaCl, 134 mM; KCl, 5 mM; KH $_2$ PO $_4$, 1.25 mM; MgSO $_4$, 2.0 mM; CaCl $_2$, 1 mM; NaHCO $_3$, 16 mM; glucose, 10 mM) containing 10 $^{-4}$ M bacitracin. The slices were transferred and gently agitated at 37 °C in 3 ml of saline, or 3 ml of saline and 10 $^{-4}$ M bacitracin, containing 6 \times 10 6 c.p.m. of iodinated C fragment (about 2 Ci mmol $^{-1}$). After 4 h incubation an equal volume of glacial acetic acid was added to the supernatant and gel filtration was performed on Sephadex G-50 (150 \times 0.9 cm) in 50% (v/v) acetic acid. The eluate fractions (2.2 ml) were monitored for radioactivity. The arrows indicate the elution positions of authentic 125 I or 125 I-labelled peptides.

Fig. 3 Identification of γ -endorphin as the first degradation product formed from C fragment in striatal slices. The peptide fraction Peak I, obtained by gel filtration of [125 I] C fragment incubated with a striatal slice in the presence of bacitracin, was concentrated *in vacuo* and chromatographed together with [131 I] γ -endorphin on SP Sephadex C-25 in 0.05 M phosphate pH 4.5 with a linear gradient from 0 to 0.5 M NaCl (200-ml mixer). The elution positions of the 61-73, 61-76, 61-77 and 61-78 peptides were established by chromatography of standard mixtures containing 125 I- or 131 I-labelled peptides.

no enrichment of labelled peptide could be detected in the slices; but the results do not preclude the possibility that formation of Met-enkephalin and the endorphins might also occur intracellularly.

Our results show that the extracellular metabolism of C fragment takes place in a specific manner to form the series of opiate-like peptides that have been isolated from brain. This may mean that the shorter peptides that have been isolated are degradation products of C fragment rather than natural peptides. It is, however, too early to be certain about this since it has been reported that enkephalin is present in rat brain even after rapid killing by microwave irradiation¹⁸.

We thank Dr A. F. Bradbury for synthesising Met-enkephalin

Fig. 4 Identification of Met-enkephalin as the principal component of the small peptide fraction formed by degradation of C fragment in striatal slices. The peptide fraction Peak II, obtained by gel filtration of [125 I]C fragment incubated with a striatal slice in the presence of bacitracin, was evaporated *in vacuo* and chromatographed on Sephadex G-15 (150 \times 0.9 cm) in 50% (v/v) acetic acid, fraction size 1.4 ml. The column was calibrated with [125 I]C fragment, the heptapeptide (61-67) and Met-enkephalin (61-65).

and the heptapeptide 61-67, and D. E. Massey for technical assistance.

Identification of the herpes simplex virus DNA polymerase gene

THERE is at present much interest in the herpes viruses because they have been associated with human cancer and cause latent infections with recurrent disease. They are also of interest because they form a relatively simple but apt model for the processes of transcription and DNA replication in eukaryotic cells. We have studied the virus-induced proteins involved in DNA replication, and present here results that give definitive evidence that the virus-induced DNA polymerase is encoded in the virus genome, that locate the gene for virus DNA polymerase, and also show that the enzyme is essential for virus replication.

Keir and Gold¹ demonstrated that herpes simplex virus (HSV) induced a DNA polymerase and Keir *et al.*^{2,3} showed that the enzyme was stimulated by high salt concentrations and inhibited by antiserum to virus-infected cells. Weissbach *et al.*⁴ demonstrated partial purification of the enzyme and more recently, we have purified the enzyme to the point where a virus-induced protein of molecular weight 149,000 can be associated with this activity⁵. Aron *et al.*⁶ and Purifoy and Benyesh-Melnick⁷ showed that HSV mutants in several complementation groups were deficient in induction of the DNA polymerase and, further, that some of these mutants induced an enzyme which was temperature sensitive *in vivo* but not *in vitro* in crude extracts.

We have been studying the DNA polymerase induced by one of these temperature-sensitive mutants of HSV type 1 (HSV-1) which is designated tsD9 (ref. 8) and by a spontaneous ts⁺ revertant of this mutant, designated DR3 (ref. 9). The purification of the enzyme from HEp-2 cells infected with this mutant at the permissive temperature is shown in Fig. 1. The details of this purification scheme and its evaluation will be published elsewhere, but suffice to say here that the mutant enzyme behaves exactly as the wild-type enzyme during purification, both in chromatographic behaviour and in the amounts of the starting

enzyme recovered (10–15% overall yield). Enzyme was purified in precisely the same manner both from cells infected with the wild-type virus (HSV-1 strain KOS) and from cells infected with the revertant, DR3. All the enzymes were neutralised specifically by antiserum to virus-infected cells.

Fig. 1 Purification of virus-induced DNA polymerase from tsD9-infected cells. Enzyme was extracted from virus-infected cells as described previously¹³, using a high salt procedure. Total enzyme activity was extracted, dialysed against 50 mM Tris-HCl, pH 7.5, 20% glycerol, 0.2% NP40 and 0.5 mM dithiothreitol (DE buffer), and applied to a DEAE-cellulose column equilibrated in the same buffer. The enzyme was adsorbed to the column and then eluted with DE buffer containing 0–0.3 M KCl. DNA polymerase activity was detected in column fractions using our standard assays for the virus-induced enzyme containing 100 mM KCl in the reaction mixture⁷. The enzyme eluted at between 0.1 and 0.15 M KCl as shown (a). The partially purified enzyme was diluted in DE buffer and applied to a phosphocellulose column equilibrated in the same buffer and prewashed with 500 $\mu\text{g ml}^{-1}$ bovine serum albumin (BSA). The column was developed with DE buffer containing 0.1–0.4 M KCl and the enzyme eluted at 0.25–0.3 M KCl (b). The activity peak from this column was dialysed against DNA cellulose buffer (DNB, 50 mM Tris-HCl, pH 7.5, 50 mM KCl, 20% glycerol, 0.2% NP40, 0.5 mM dithiothreitol, 1 mM EDTA) after adjusting the protein concentration to 500 $\mu\text{g ml}^{-1}$ with BSA. The dialysed enzyme was applied to a DNA-cellulose column equilibrated with DNB and eluted in stepwise fashion with 0.05, 0.1, 0.2, 0.4, and 1.0 M KCl in the same buffer. Purified enzyme eluted with 0.4 M KCl (c) and was then used for further experiments.

Fig. 2 Heat inactivation of purified enzymes. DNA polymerase purified from wild-type (●), mutant tsD9 (△), or revertant DR3 (○) infected cells was heated at 39 °C for various times in reaction mixture, then template DNA was added and the residual DNA polymerase activity determined using standard assay methods. The specific activity of the enzymes was between 4,000 and 5,000 units mg^{-1} (1 unit is defined as 1 nmol TTP incorporated h^{-1}). One hundred per cent activity corresponds to 70,000 c.p.m. in this assay for each enzyme.

The next step was to test the thermal inactivation of the purified enzymes from mutant, revertant, and wild-type virus-infected cells in the absence of DNA template. In these experiments, purified enzyme (specific activity approximately 4,500 units mg^{-1}) was incubated at 39 °C in reaction mixture without DNA for various periods, template was added and the residual DNA polymerase activity determined. The results presented in Fig. 2 demonstrate that DNA polymerase induced by wild-type virus and revertant is considerably more stable than that induced by the mutant. This result has been verified with batches of enzyme from several independent purifications. Thus, the temperature-sensitive mutation in tsD9 directly affects the DNA polymerase induced by the mutant, causing a loss in the stability of the enzyme; reversion of the mutation is accompanied by recovery of that stability.

HSV replication has been shown to be inhibited by the drug, phosphonoacetic acid¹⁶. Further mutants of the virus have been isolated which are resistant to the drug, and this resistance correlates with DNA polymerase activity in crude extracts *in vitro* (refs 11 and 12). TsD9 was not selected for phosphonoacetic acid resistance and yet is resistant to the drug (ref. 9). To confirm this observation and further to correlate the sensitivity or resistance of the enzyme to phosphonoacetate, it was essential to test

purified enzyme. This experiment has been done and the results are shown in Fig. 3. Purified DNA polymerase from wild-type or DR3 (revertant)-infected cells was extremely sensitive to the drug: 50% inhibition of the enzyme activity was observed at a drug concentration of $0.5\text{--}1\text{ }\mu\text{g ml}^{-1}$. With the purified mutant enzyme a 10–20-fold higher concentration of the inhibitor was required to inhibit the enzyme activity. Reversion of the temperature-sensitive lesion again resulted in restoration of wild-type characteristics to the mutant enzyme.

Our results demonstrate that the temperature-sensitive mutation in the HSV-1 tsD9 genome elicits altered characteristics of the virus-induced DNA polymerase, namely temperature sensitivity and phosphonoacetic acid resistance. Since tsD9 has been located on the virus genetic map between tsO22 and tsN20 (P. A. Schaffer, personal communication), our results enable the virus DNA polymerase gene to be positioned on the current genetic map. Marker rescue with restriction enzyme fragments of tsD9 will enable the location of the DNA coding for the enzyme on the physical map of virus DNA. Several other conclusions can be drawn from the data. First, the virus codes for the induced DNA polymerase, which is the first direct evidence for an animal virus specified DNA-dependent DNA polymerase. We suggest that this polymerase be designated pol H, to distinguish it simply from host cell enzymes. Second, the DNA polymerase activity is essential for virus DNA replication and growth, since tsD9 does not replicate DNA at the non-permissive temperature. Third, phosphonoacetate resistance, at least in this case, is conferred on the virus by changes in the structure of its DNA polymerase—

thus providing a useful method for selection of temperature-sensitive mutants in the viral enzyme.

We thank Ms Beth Gingerich and Mr Ira Wimberley for technical assistance. We are grateful to Drs P. Schaffer and G. Aron for the original stock of mutant tsD9, to Abbot Laboratories for the gift of the phosphonoacetic acid, and to Dr S. Kit for reading the manuscript. This study was supported by a grant from the NCI.

Fig. 3 Phosphonoacetic acid (PAA) sensitivity of purified enzymes. DNA polymerase purified from wild-type (●), mutant tsD9 (△), or revertant DR3 (○) infected cells was assayed in the presence of various concentrations of PAA. One hundred per cent activity corresponds to about 120,000 c.p.m. in this assay.

Sister chromatid exchange and chromatid interchange as possible manifestation of different DNA repair processes

SISTER chromatid exchange (SCE) is a symmetrical exchange between a newly duplicated chromatid and its sister¹. The demonstration that many agents that damage DNA also increase the frequency of SCE² suggests that SCE is a reflection of a basic DNA repair process, and perhaps a cytological manifestation of post-replication repair of a recombinational character^{2–6}. The question then arises as to the correlation between SCE and chromatid aberration, particularly chromatid interchange (CI), which also occurs as a consequence of exchange between newly duplicated chromatids^{7,8}. To investigate whether these two types of exchange are due to the same molecular event, I have studied the reaction of SCE and CI to caffeine and cycloheximide in endoreduplication mitoses of cultured human embryonic skin fibroblasts. I report here evidence suggesting that the events involved are separate.

Endoreduplication is an internal doubling of chromosomes resulting from two successive DNA synthesis periods without intervening cytokinesis. Sister chromosomes are paired to form a diplochromosome. When the cells are grown for two replication cycles in the presence of 5-bromodeoxyuridine (BUDR) so that chromosomes can be stained differentially to distinguish one chromatid unifarly with BUDR from its sister bifarly substituted, three types of exchange can be seen—twin SCE occurring in the first S phase, single SCE occurring in the second S phase and intradiplochromatid interchange (IDCI) which occurs between chromosomes in a diplochromosome (Fig. 1).

Fibroblast cultures established from skin fragments of 9–11-week-old human abortuses were used at passages 4–7. Confluent cultures were trypsinised and the cells were grown in Leibovitz's L-15 medium containing 15% foetal calf serum and 20 μM BUDR. Cells were fixed for chromosome

Fig. 1 Diagram of SCEs and IDCIs in diplochromosomes and orderly segregation of DNA strands during the replication cycle. The diagram is based on the unimere model of chromosomes, in which a chromatid contains a single DNA duplex. The new DNA strands always segregate outside the parental strands. When the cells are grown in the presence of BUdR for two replication cycles, except for disruption by exchanges, the chromatids of unifilar BUdR-substitution (TB) are on the inner side in diplochromosomes while those of bifilar BUdR-substitution (BB) are on the outer side. Broken lines represent BUdR-substituted DNA strands and solid lines unsubstituted grand-parental strands. Arrows show the sites of exchanges.

preparations 70 h after plating—mitotic arrest was achieved by a 4-h prefixation with colcemid. The effects of caffeine and cycloheximide were studied by treating cells for the last 24 h. In some cultures, 0.005% β -mercaptoethanol was added to increase the frequency of endoreduplication mitoses. Chromosome preparations were processed for differential chromatid staining according to the 'fluorescent plus Giemsa' technique of Perry and Wolff⁹, and endoreduplication mitoses (Fig. 2) were analysed for types and frequencies of SCEs and IDCIs.

Figure 3 shows that incubation in the presence of β -mercaptoethanol increased the frequency of twin and

Fig. 2 Endoreduplication mitosis with differential chromatid staining showing single SCEs (single arrows), twin SCEs (double arrows) and IDCIs. The cell was exposed overnight to a black-light fluorescent lamp (Toshiba FL20BL) in 33258 Hoechst $1 \mu\text{g ml}^{-1}$, incubated in distilled water for 2 h at 62 °C and stained with Giemsa. Bifilarly BUdR-substituted chromatids are stained light while unifilarly substituted ones are stained dark.

single SCEs but did not affect that of IDCIs. In the untreated cultures, either with or without β -mercaptoethanol, the rates of SCE in the first and second S phases were approximately the same, the number of twin SCEs per diplochromosome not being significantly different from the number of single SCEs per chromosome. Because the treatment for the last 24 h covers only the second replication cycle in my culture conditions¹⁰, twin SCEs related with the first S phase could not be influenced by caffeine and cycloheximide treatment during this interval. But exchange events relating to the second S phase, that is, single SCEs and IDCIs, were significantly affected by these compounds, although in different ways—caffeine reduced IDCIs but increased single SCEs, whereas cycloheximide had no effect on IDCIs but suppressed single SCEs. The involvement of chromatids in the formation of IDCIs was non-random. Of 565 IDCIs scored, 518 (91.7%) were exchanges between chromatids with uni- and bifilar substitution (TB/BB type) (Fig. 1), and the TB/TB and BB/BB types were unexpectedly infrequent, constituting only 7.8% and 0.5%, respectively. The IDCIs of TB/TB and BB/BB types between chromatids with identical staining properties, could only be recognised morphologically as X-shaped criss-cross exchanges. But among IDCIs of TB/BB type, 91.3% had the same configuration of overlapping chromatids. Thus the predominance of TB/BB exchanges cannot be explained by different rates of detection, but suggests some biological significance for the formation of IDCIs in these conditions. In the cells grown in the absence of BUdR, the frequency of morphologically identifiable IDCIs was 0.02 per diplochromosome, about a quarter of that in the presence of 20 μM BUdR, which apparently induces IDCI.

It is interesting that IDCIs can be suppressed by caffeine. Caffeine inhibits post-replication repair¹¹⁻¹³, which is thought to involve the formation of gaps in the daughter strand during replication on a damaged DNA template and the filling in of these gaps by *de novo* synthesis¹⁰. Similar processes and/or types of lesion are likely to be responsible for CI formation, possibly through a recombinational event. In eukaryotic cells, cycloheximide causes immediate inhibition of DNA replication¹⁷⁻¹⁹. Although the action of cycloheximide may be diverse²⁰⁻²¹, it is tempting to correlate the

cycloheximide-sensitive SCE with some components of the DNA replication process.

Although my study concerned chromatid exchange in diplochromosomes, it is possible that the process responsible for IDCI formation occurs during normal diploid mitosis. This would manifest as false SCE²²⁻²³ when occurring between sister chromatids and would give rise to CI and other chromatid exchange aberrations if chromosome segments involved are closely positioned in the nucleus and replicate at a similar time. In spite of the general association between SCEs and chromatid aberrations in their response to DNA-damaging agents, there is evidence against a correlation between two phenomena. Among human genetic diseases known to be characterised by a high frequency of spontaneous chromatid aberrations, only Bloom's syndrome involves apparent association of the two, showing an abnormally high rate of spontaneous SCE²⁴. But in

Fanconi's anaemia²⁵, ataxia telangiectasia²⁶ and incontinentia pigmenti (my unpublished data) the rate of SCE is normal. Moreover, in Fanconi's anaemia²⁵ and xeroderma pigmentosum²⁷, sensitivity to SCE caused by chemical mutagens does not correlate with the sensitivity to chromatid aberration formation, whereas IDCI formation does²⁸. Also the effects of caffeine on chemical induction of SCE differ in plants²⁹ and Chinese hamster cells⁴. These lines of evidence reinforce my conclusion that there is a two-step, replication-mediated, repair mechanism and that SCE and CI are cytological manifestations of them. The relative potential of each process may vary with the types of DNA damage, repair systems and organisms involved.

This work was supported by grants from the Ministry of Education, Science and Culture, and the Ministry of Health and Welfare of Japan. I thank Dr H. Loewe, Hoechst, Frankfurt, for fluorochrome 33258.

Fig. 3 Effects of caffeine and cycloheximide on frequencies of SCE and IDCI. Experiments were done in the presence (circles) or absence (squares) of β -mercaptoethanol. Solid symbols, cycloheximide, open symbols, caffeine. Each point is based on 12-25 endoreduplicated mitoses.

Long-term persistence of O^6 -methylguanine in rat brain DNA

THE carcinogenic potency of alkylating agents correlates with the extent of their reaction at oxygen atoms in DNA bases¹. O^6 -Alkylguanine is amongst those derivatives most likely to be involved in the initiation of malignant transformation since it leads to mispairing *in vitro* and thus can be considered promutagenic^{2,3}. Repair excision of O^6 -alkylguanine from DNA has been demonstrated in bacteria⁴ and mammalian cells⁵, and seems to be initiated by a specific *N*-glucosidase⁶. In the intact animal, the persistence of O^6 -alkylguanine in DNA of different tissues varies considerably. In rats, the induction of neural^{7,8} and renal⁹ neoplasms correlates with a deficient excision capacity of the respective target tissues. O^6 -Alkylguanine produced by a single injection of the neuro-oncogenic agents *N*-ethyl-*N*-nitrosourea and *N*-methyl-*N*-nitrosourea (MNU), is removed

from brain DNA significantly more slowly than from that of liver and kidney, the half life in cerebral DNA being in the range of 9–11 d for both *O*⁶-ethyl- and *O*⁶-methylguanine^{7,10}. These data are, however, based only on observations for up to 10 d. We report here that the decay curve for *O*⁶-methylguanine in brain DNA consists of different components and that this modified base may persist in cerebral DNA for a considerable fraction of the animal's life.

Adult female BD-IX rats (100–120 g) received a single intravenous injection of *N*-[³H]-methyl-*N*-nitrosourea (25.5 mCi mmol⁻¹) at a dose of 10 mg per kg body weight. After time intervals ranging from 4 h to 184 d, DNA was isolated by phenol extraction¹¹ from the combined organs of two animals. Following hydrolysis in 0.1 M HCl (37 °C, 24 h) purine bases were separated on Sephadex G-10 columns (1 × 90 cm) using 0.05 M ammonium formate (pH 6.2) as eluent. The amounts of methylated purines were expressed as a fraction of the parent base, assuming that the specific radioactivity of the methyl group was identical to that of the injected carcinogen¹².

The persistence of *O*⁶-methylguanine in DNA of various rat organs is shown in Fig. 1. Excision from hepatic DNA was faster than from that of any other tissue, *O*⁶-methylguanine concentrations being below the level of detectability within 7 d. In lung and kidney DNA, the limit of detection was reached by 28 and 84 d respectively. In brain, the rate of excision was considerably slower. Following a rapid decrease during the first hours after injection, there is a distinct slope extending from 12-h to 14 d. During this period, *O*⁶-methylguanine values were reduced from 78% to 50% of the initial (4 h) concentration. Subsequently, the rate of removal decreased greatly. In contrast to the other organs and to the initial part of the decay curve for the nervous system, this latter component was linear. At 184 d, 25% of the initial concentration was still present in cerebral DNA. Extrapolation of these data suggests that complete removal of *O*⁶-methylguanine would require approximately 1 yr.

We can rule out the possibility that tissue-dependent variations in cell turnover significantly account for the observed differences in the rate of loss of *O*⁶-methylguanine from DNA. 7-Methylguanine which is removed non-enzymatically from DNA by hydrolysis, shows a similar decay in both liver and brain (Fig. 2).

The dose of MNU used in this study (10 mg per kg) represents approximately 10% of the 50% lethal dose (LD₅₀) and is not sufficient to induce tumours. Given

Fig. 1 Persistence of *O*⁶-methylguanine in DNA of brain (●), kidney (△), lung (▽), and liver (○). Female BD-IX rats received a single intravenous injection of *N*-[³H]-methyl-*N*-nitrosourea (10 mg kg⁻¹) and were killed at time intervals ranging from 4 h to 184 d.

Fig. 2 7-Methylguanine concentrations in DNA of rat brain (●) and liver (○) following a single injection of ³H-MNU. Experimental details as in Fig. 1.

repeatedly, however, it will produce primarily tumours of the nervous system. In contrast to other organs, such multiple doses lead to a linear increase of *O*⁶-methylguanine in brain DNA¹¹. It now seems that this additive effect is based on the linear (slow) segment of the excision curve. It is possible, however, that different excision kinetics apply to alkylated bases resulting from environmental exposure to very small doses. In rat liver, the rate of excision has indeed been shown to be inversely related to the initial amount of *O*⁶-methylguanine produced^{13,14}.

The different components of the *O*⁶-methylguanine removal curve in rat brain may represent DNA fractions within the chromatin complex having a different accessibility to repair enzymes¹⁵. Alternatively, the different slopes may reflect the repair capacity of different brain cell populations, for example neuronal versus glial cells. The latter possibility is being investigated. If the persistence of *O*⁶-alkylguanine in DNA leads to mutational events responsible for malignant transformation, the slow component should represent glial DNA, since the tumours induced by MNU and related carcinogens are almost exclusively of glial origin.

Daunorubicin and adriamycin facilitate actinomycin D binding to poly(dA-dT)·poly(dA-dT)

ACTINOMYCIN D (Fig. 1a) binds to DNA by intercalation of the phenoxazone ring between adjacent base pairs of the double helix¹⁻⁴. There is a general requirement for a guanine base at the actinomycin D binding site on DNA, as illustrated by the observation that actinomycin D does not intercalate into double-stranded (ds) poly(dA-dT)·poly(dA-dT) (refs 1-4). Daunorubicin, adriamycin (Fig. 1b) and ethidium bromide (Fig. 1c) also intercalate into dsDNA, but in contrast to actinomycin D, these drugs do not show any requirement for a particular base at the intercalation site^{5,6}. Both actinomycin D and ethidium bromide do, however, show definite preferences for binding to certain sequences of nucleic acid bases at the intercalation site⁷⁻¹¹. In this report we show that daunorubicin and adriamycin facilitate strong binding of actinomycin D to poly(dA-dT)·poly(dA-dT) and we discuss the implications of this new observation.

Circular dichroism (CD) spectroscopy is a particularly sensitive technique for monitoring the formation of a complex between drugs and nucleic acids. Both daunorubicin and actinomycin D are optically active and give rise to circular dichroism spectra which undergo characteristic changes when these drugs bind to DNA, synthetic polynucleotides, or oligonucleotides (refs 6, 12-19 and our unpublished observations). The intercalated complex of actinomycin D with DNA is characterised by a large negative band in the 440-490-nm region, whereas actinomycin D in dilute aqueous solution or in solution with poly(dA-dT)·poly(dA-dT) has only a negligible band in this region (Fig. 2). Daunorubicin and adriamycin exhibit a broad weak positive CD band in the 440-480-nm region,

which is intensified following binding to DNA or poly(dA-dT)·poly(dA-dT) (Fig. 2). The circular dichroism spectra of poly(dA-dT)·poly(dA-dT) with daunorubicin or actinomycin D, and of an equimolar mixture of the two drugs with poly(dA-dT)·poly(dA-dT) are also shown in Fig. 2. The appearance of the strong negative band in the 450-490-nm region of the spectrum of the equimolar mixture of the two drugs with poly(dA-dT)·poly(dA-dT) results from the simultaneous binding of these two drugs to poly(dA-dT)·poly(dA-dT). The intensification of the 380-nm band of actinomycin D when it binds to poly(dA-dT) (which is readily apparent in the difference spectrum shown in Fig. 2) also indicates that daunorubicin cooperatively facilitates the binding of actinomycin D to poly(dA-dT)·poly(dA-dT). We believe that this is the first example of co-operative binding between two intercalating drugs. Ethidium bromide intercalates into poly(dA-dT)·poly(dA-dT), but circular dichroism spectra indicate that ethidium bromide does not facilitate the binding of actinomycin D to poly(dA-dT)·poly(dA-dT), nor does the addition of actinomycin D significantly influence the binding of ethidium bromide to this polynucleotide (T.R.K., M.A.Y. & R. V. Kastrup, in preparation). In related experiments, we have used ³H-actinomycin D in equilibrium dialysis experiments, from which we estimate that the association constant for the binding of actinomycin D to poly(dA-dT)·poly(dA-dT) in the presence of daunorubicin is $\sim 4 \times 10^5 \text{ M}^{-1}$ (T.R.K., W. E. Moehle & K. G. Rao, in preparation).

These results raise several important questions. First, how does daunorubicin (or adriamycin) enhance the binding of actinomycin D to poly(dA-dT)·poly(dA-dT)? Intercalation of these drugs unwinds the DNA helix¹⁻⁶ and it is likely that the distortions induced in the double helix may be transmitted over several base pairs. The amino sugars of daunorubicin and adriamycin, and the cyclic pentapeptides of actinomycin D become located along the grooves of the double helix when the planar portions of the drugs (Fig. 1) intercalate between the base pairs. The

Fig. 1 The chemical structures of a, actinomycin D; c, ethidium bromide; and b, daunorubicin (also frequently called daunomycin) and adriamycin.

R = H Daunorubicin

R = OH Adriamycin

changes in the double helical geometry of poly(dA-dT)·poly(dA-dT) which accompany daunorubicin binding are presumably responsible for the facilitation of actinomycin D binding to an adjacent region of poly(dA-dT)·poly(dA-dT).

Thus the present results show that when daunorubicin binds to poly(dA-dT)·poly(dA-dT) a change occurs in the conformation of the polynucleotide at an adjacent region of

Fig. 2 Circular dichroism spectra of solutions of: *a*, 8.5×10^{-6} M daunorubicin (DR) and actinomycin D (Act D) alone and in the presence of 8.5×10^{-6} M DNA; *b*, 8.5×10^{-6} M daunorubicin plus 8.5×10^{-6} M poly(dA-dT)·poly(dA-dT); 8.5×10^{-6} M actinomycin D plus 8.5×10^{-6} M poly(dA-dT)·poly(dA-dT); 8.5×10^{-6} M actinomycin D plus 8.5×10^{-6} M daunorubicin plus 8.5×10^{-6} M poly(dA-dT)·poly(dA-dT). The curve was calculated by subtracting the poly(dA-dT)·poly(dA-dT)+DR spectrum from the poly(dA-dT)·poly(dA-dT)+DR+Act D spectrum which, to a first approximation, is an estimate of the circular dichroism spectrum of actinomycin D when bound to poly(dA-dT)·poly(dA-dT). All spectra were recorded on a Jasco J-40 circular dichroism instrument in a 4-cm path length cell at 20 °C. All solutions contained 10 mM potassium phosphate buffer, pH 7.0. Essentially similar results were obtained at lower drug-to-phosphate ratios, as well as in the presence of 0.1 M NaCl. The spectra in which adriamycin were used in place of daunorubicin gave qualitatively similar results. 7-Amino-actinomycin D has also been used in place of actinomycin D with qualitatively similar results. The circular dichroism spectra in which ethidium bromide is used in combination with actinomycin D and poly(dA-dT)·poly(dA-dT) do not show the appearance of the large negative band in the 440–480-nm region. The circular dichroism spectrum (*a*) of a daunorubicin and actinomycin D solution (8.5×10^{-6} M in each drug) is not equal to the sum of the circular dichroism spectra of the individual drugs (data not included) at all wavelengths, which shows that a small fraction of the daunorubicin and actinomycin D molecules form a heterodrug complex. These small effects do not influence the present results, however, or the interpretation of the data presented here because >90% of the drugs are bound to poly(dA-dT)·poly(dA-dT) when the polynucleotide is present, and thus the concentrations of the free drugs are $<1 \times 10^{-6}$ M in the presence of the polynucleotides, which essentially eliminates the formation of drug–drug aggregates. We have also studied the binding of actinomycin D and daunorubicin to poly(dA), poly(dT), and a poly(dA)·poly(dT) duplex, where we observed the synergistic binding of the two drugs only in the presence of the ds polynucleotide, poly(dA)·poly(dT). No cooperative binding of the drugs was observed when the ribopolynucleotide poly(A-U)·poly(A-U) was used, which is not surprising because actinomycin D does not bind to polyribonucleotides^{1–4} and daunorubicin has been previously reported to bind only weakly to polyribonucleotides⁶.

the double helix which results in an increase in the stability of the actinomycin D–poly(dA-dT)·poly(dA-dT) complex. This transmission of the distortions of the nucleic acid conformation along the double helix may also be an important component in the selective recognition of nucleic acid sequences (as for example, in promoter–operator complexes), and is related to the transmission of thermal stability from the G-C region to the A-T region which has been observed in block oligonucleotides such as d(C₁₅A₁₅)-d(T₁₅G₁₅) (refs 20–22).

Second, do daunorubicin and actinomycin D (or adriamycin and actinomycin D) both intercalate into poly(dA-dT)·poly(dA-dT)? The shape of the circular dichroism spectra in Fig. 2 suggests that both chromophores are intercalated, but nuclear magnetic resonance experiments on complexes of these drugs with oligonucleotides are required to verify the geometry of the complexes^{8,23,24}.

Third, will these drugs bind cooperatively to DNA *in vivo*, and more important, will they exhibit a synergistic physiological activity if used in combination? *In vivo*, the primary mode of action of the intercalating drugs has been shown to be interference with the nucleic acid polymerases (see refs 25 and 26). In separate experiments (A. H. McHale, S. S. Holcomb, R. Josephson & T.R.K., in preparation) we have observed that actinomycin D does not inhibit the activity of *E. coli* DNA polymerase when poly(dA-dT)·poly(dA-dT) is used as a template, whereas daunorubicin and adriamycin give rise to the anticipated dose–response curves for the inhibition of this enzyme as a function of the drug concentration^{1–4,6,25,26}. The presence of actinomycin D does, however, affect the daunorubicin inhibition of poly(dA-dT)·poly(dA-dT) synthesis, which also illustrates the synergistic interaction of the two drugs when both are bound to poly(dA-dT)·poly(dA-dT). We have been unable to find reports of clinical studies involving the combined use of either daunorubicin or adriamycin with actinomycin D either by themselves or with other drugs. The results reported here suggest that combinations of these drugs should be explored clinically.

We thank R. V. Kastrup and K. G. Rao for assistance with parts of this research. This work was supported by research grants and a Research Career Development Award (to T.R.K.) from the National Cancer Institute. T.R.K. is an Alfred P. Sloan Fellow.

reviews

Imaginative immunology

Maria de Sousa

B and T Cells in Immune Recognition. Edited by F. Loor and G. E. Roelants. Pp. xviii + 504. (Wiley-Interscience: New York and London, 1977.) £18.50; \$37.50.

A RATHER unimaginative title for a rare, imaginative immunology book.

The editors, Francis Loor and Georges Roelants, members of the staff of the Basel Institute of Immunology for long enough to reflect its eclectic atmosphere in their choices, bring together twenty chapters that leave out little that is relevant to those concerned with the way cellular immunology is going.

No complement, gut immunology or parasite diseases. Otherwise, those interested in autoimmunity, immunodeficiency, lymphoproliferative malignancy, HLA-associated disease, cell-mediated cytotoxicity, the major histocompatibility complex (MHC) its role in lymphocyte activation and its relevance to transplantation in man, will find competent chapters by Fye, Moutsopoulos and Talal (autoimmunity), Cooper and Seligman (immunodeficiency and lymphoid malignancy), Ryder and Sveigaard (HLA-associated disease), Dausset and Fradelizi (MLR genes and transplantation), Cerottini and Brunner (cell-mediated cytotoxicity) and Bluestein (MHC and lymphocyte activation).

Those wondering whether immunology still has anything to do with the understanding and therapy of cancer will find a concise review of the current state of the clinical and experimental art by Mitchison.

But there is also information for the developmental immunologist. From the wider biological world of LeDouarin, who candidly admits that "the actual immunological function of the thymus is well documented only for Aves and Mammals; only little information has been produced concerning the thymus equivalent organs found in other vertebrates". From the ontogeny perspective of Owen who concludes his chapter on "Ontogenesis of lymphocytes" with the remark that "many basic questions of immunology are essentially problems of lymphocyte differentiation", a remark that gains reality as one wanders through Beverley's chapter on "lymphocyte heterogeneity".

The role of thymic hormones is reviewed by Trainin, Small and Kook. But should one forget that immunology is only T or B cells, an excellent chapter by Roelants reminds us of "the regulatory role of macrophages in immune recognition". This is not the only healthy reminder of the variety of present day immunology.

Lymphocytes "go round", a frequently forgotten event competently reviewed by Sprent in a chapter on "migration and lifespan of lymphocytes"; the chapter by Schreier and Nordin entitled "An evaluation of the immune response *in vitro*" is certain to become a classical chapter of twentieth century immunological literature. This is the only chapter in the book from which the editors requested original data (we are told in the preface). Their intention was to illustrate how cautious one must be with *in vitro* experiments on the immune response. In it, one learns how varying rocking, feeding and adding mercaptoethanol to cell cultures placed in different dishes, leads five different investigators to being equally right in their five different conclusions.

Humour is not restricted to this latter chapter. Parkhouse and Abney's chapter on "Biochemical approaches to receptors for antigen on B and T

lymphocytes" has both humour and sufficient facts and arguments to help readers find their way through an area of much controversy, separately reviewed by Goodman in the chapter on "The specificity repertoire and antigen receptors of T and B lymphocytes".

It is the reviewer's own bias and interest to find evidence of roots of future in present day texts, that leads me to conclude by stressing the importance of the four most enlightening chapters: Loor's on "Structure and dynamics of the lymphocyte surface", Klaus' on "B cell maturation", Nabholz and Miggiano's on "The biological significance of the MLR", and Bretscher's closing chapter integrating T and B lymphocytes in immune activation.

Some minor printing errors: One wonders, for instance if Avron Mitchison (p 338) did mean to say that "modern immunology starts with Foley and Prehn and Main", knowing with all due respect, who else (including himself) was around at the time.

A rare and imaginative immunology book indeed. □

Quark binding

Quark Confinement and Field Theory. Edited by D. R. Stump and D. H. Wein-garten. Pp. 253. (Wiley: London, New York and Tokyo, 1977.) £18.70; \$31.70.

THIS book offers a collection of papers presented at the workshop on quark binding held at the University of Rochester in June, 1976. The papers represent a cross section of current work on quark confinement and field theory.

Various approaches to the study of collective phenomena, and classical solutions to Yang-Mills field equations are found in papers by Y. Nambu, T. Eguchi, K. Huang and D. Stump, and F. Wilczek. In an attempt to understand a different class of non-perturbative phenomena, N. Snyderman and G. Guralnik discuss dynamical symmetry breaking.

In two closely related papers, E. Poggio and J. Carrazzone give summaries of their analyses of high orders in perturbation theory for Yang-Mills theories. The stumbling block of this method is, of course, a lack of knowledge about the infrared behaviour of the effective quark-gluon coupling strength. In another paper, P. Olesen offers a description of some aspects of this behaviour using a clever application of the renormalisation group.

Theoretical descriptions of particles produced in e^+e^- annihilation are offered in three papers. V. Matveev presents a phenomenological hydrodynamic model of collective resonances, a model which he suggests may have applications in the description of e^+e^- production of resonances. A more conventional model is used to describe charmonium by T. Yan. Yan presents

an excellent analysis using an effective field theory with a linear potential. A phenomenological model which attempts to describe charmed particle decays is presented by V. Mathur.

Each of the remaining three papers deals with areas with little connection to other work presented at the conference. In a discussion of covariance problems in two dimensions, C. Hagen questions the validity of light cone field theory. Deviations from scaling are analysed by H. Politzer, using the renormalisation group and the Wilson operator product expansion. An unconventional model involving massive gluons and unconfined colour is presented by R. N. Mohapatra as a possible explanation of high γ anomalies and dimuon events. (It should be noted

that recent experimental work, not yet made public at the time of publication of this collection, offers no evidence for the phenomena this paper attempts to explain.)

This book contains some excellent reports on theoretical work on the quark binding problem and field theory, and would be appropriate for the shelves of physics libraries. For those who are actively working in these areas, however, purchase of this book seems an expensive way to acquire papers which are readily available either as reprints or as published articles.

Larry McLerran

Larry McLerran is a research associate in the Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts.

Fungal symbiosis

The Biology of Symbiotic Fungi. By Roderic Cooke. Pp. xi+282. (Wiley: London and New York, 1977.) \$21; £10.75.

THE word *Symbiotic* in the title of this book is used in a much broader sense than most botanists have used it in recent years. Instead, the author adopts the older usage of de Bary, recently introduced again by D. H. Lewis, using the term symbiosis to include any association between two organisms which involves long-term intimate contact. This includes, therefore, both antagonistic (parasitic) relationships as well as the mutualistic relationships most commonly considered by botanists to be symbiosis. The author recognises that some relationships exist which cannot with certainty be classified as antagonistic or mutualistic, and these he calls neutral. Neutral symbioses are particularly important in associations of fungi with animals.

Symbiotic relationships between fungi and animals, fungi and higher plants, fungi and algae (lichens) and between fungi and other fungi, are all considered. As explained above, these are classified as antagonistic, neutral or mutualistic relationships; further, the fungi are divided on nutritional grounds, again following D. H. Lewis, into necrotrophic and biotrophic species. In this connection it may be mentioned that the author recognises—and this will be welcomed by many plant pathologists—that quite a number of plant-pathogenic fungi are not easily characterised as necrotrophs or biotrophs; some seem to start their association with their host plant as

biotrophs, finishing up as necrotrophs, and these are classified in this book as a distinct group, hemibiotrophs.

A very wide range of possible associations are thus considered; examples are discussed in each category with particular reference to nutritional and other physiological relationships between the two symbiotic associates. Five chapters are devoted to symbioses with animals and six chapters to symbioses between fungi and plants, including the lichen symbiosis. Since much more is known about fungus-plant symbioses than fungus-animal symbioses, one might expect that the inevitably more 'concentrated' material which appears in the chapters dealing with plants would lead to a degree of imbalance. This is not the case; the book gives a strong impression of unity, and this is all the more valuable in that it covers a range of topics which have never before been brought systematically together.

Indeed, it is striking how similar, in many respects, the fungi involved in biotrophic associations with animals are to those similarly involved with plants. To take one example, it seems to be very common among biotrophs in both situations that they are difficult to culture axenically. This characteristic may become less noticeable as cultural techniques improve, but at present it is quite striking.

This is undoubtedly a valuable book covering a wide field. It will be of interest not only to mycologists, but also to all botanists and zoologists interested in fungal symbiosis. Not many students will be able to afford it—let's hope that it is widely bought by departmental libraries.

P. W. Brian

P. W. Brian has just retired as Professor of Botany at the University of Cambridge, UK.

Introducing cryobiochemistry

Cryobiochemistry: An Introduction. By Pierre Douzou. Pp. x+286. (Academic: London and New York, 1977.) £12.60; \$24.65.

PROFESSOR DOUZOU'S book on the theory and practice of low temperature biochemistry appears at a time of increasing interest in the technique, and when the first reports of it being used at its full power are beginning to appear. The aim of the technique is no less than the thermal resolution of the individual steps in biochemical processes, especially enzyme reactions, and the stabilisation of intermediates for timescales sufficient for their detailed examination by the more powerful analytical techniques. This is an exciting prospect for the molecular biochemists, and this book is doubly welcome, because not only has Professor Douzou, as the major pioneer of the field, given us the gift of his ten years of experience and development of the subject, but he has also presented it in a well written and clearly organised text.

The major experimental problem of ensuring that even in solutions of mixed solvents at temperatures down to -100°C the proteins are both structurally intact and functionally, potentially competent, is dealt with at length. The book also provides invaluable guidance in choosing solvent systems, the pH, dielectric constant and viscosity at subzero temperatures of which are closely matched with those of the normal room temperature environment. In this respect, the book fulfills the function of a laboratory handbook on low temperature procedures, with many specific examples, drawings of special apparatus and tables of physical properties of mixed solvent systems. At the same time the book reveals its origins as a lecture course, in beginning each section at the most elementary level and taking the reader step by step, from the properties of mixed solvents, through their effects on enzyme activity, to the study of biological molecules at subzero temperatures.

This is a first-class introduction in both the theoretical and practical sense to what is bound to become an increasingly important technique in biochemistry.

C. C. F. Blake

C. C. F. Blake is Lecturer in Molecular Biophysics at the University of Oxford, UK.

Hartree-Fock method

The Hartree-Fock Method for Atoms: A Numerical Approach. By C. Froese Fischer. Pp. 308. (Wiley Interscience: London and New York, 1977.) £17.20; \$29.

THE Hartree-Fock (HF) method means different things to different people. The one point in common is that a wave function Φ for a many-particle system is constructed from anti-symmetrised products of one-particle functions ϕ , and that the latter are fully optimised. In many-body theory, as used in nuclear and solid-state calculations, Φ is taken to be a single determinant.

In applications of HF theory to non-relativistic atomic structure calculations, which is the subject of this book, the condition is invariably imposed that Φ must be an eigen function of total spin and total orbital angular momentum operators. In all but the simplest cases, this condition implies that Φ must be a linear combination of several determinants. The HF approximation for atoms is sometimes taken to imply the restriction that Φ is constructed

from functions ϕ , all belonging to the same configuration (although the exact meaning of this statement is not always clear, as is illustrated by Froese Fischer's discussion of the $1s2s^2$ 'S state'). In 1939, Hartree, Hartree and Swirles showed that this restriction need not be made. They introduced the multi-configuration method (MCHF), which has been used extensively in recent years, and provides one of the most powerful known methods for calculating accurate atomic wave functions. A great deal of skill has been devoted to the development of the numerical and computational techniques required for this work, and they are clearly described in this book, which puts particular emphasis on methods using numerical integration of the equations (as opposed to those using expansions in terms of basis functions).

The book gives a lucid account of the foundations of atomic HF theory, a detailed account for the specialist of modern MCHF work, and concludes with a useful discussion of available computer programs for atomic structure calculations.

M. J. Seaton

M. J. Seaton is Professor of Physics at University College, London, UK

Dielectric relaxation

Dielectric Spectroscopy of Polymers. By Peter Hedvig. Pp. 430. (Adam Hilger: Bristol; Akademiai Kiado: Budapest, 1977.) £17.50.

IN the past decade, an attempt has been made in many laboratories to unify the study of the dielectric, mechanical and nuclear magnetic resonance (NMR) relaxations in solid polymers, into a coherent spectroscopy. The underlying desire in this attempt was to put forward an interpretation on the molecular level for the observed relaxations. Although such a unified approach has not yet been achieved, Peter Hedvig's book is an excellent up-to-date review on efforts towards this aim.

This first two chapters deal in a concise and precise way with the principles of dielectric spectroscopy and structural transitions and molecular mobilities in solid polymers. Transitions in the glassy state involving local molecular motion are discussed using the potential barrier theory. Cryogenic relaxation phenomena are presented together with the molecular level interpretation. Transitions in the crystalline phase involving defects and orientation effects are discussed, well illustrated and supported by an extensive list of references.

These are followed by three chapters

which present both the experimental techniques and results of dielectric, mechanical and NMR spectroscopies together with dilatometry and differential thermal analysis. The depolarisation technique and the new time domain method (Fourier method) are presented in detail. Dielectric spectra of both pure polymers and polymer compounds are examined both from the chemical structural point of view as well as from the point of view of 'physical' phenomena such as plasticisers and filler effects.

In the last two chapters the study of crosslinking and ageing processes by dielectric spectroscopy is presented. These chapters are unique and original in the literature, and are of special interest to those involved in the technological aspects of dielectric spectroscopy of solid polymers.

In the Appendix the relaxation maps of 31 polymers are presented. This collection is of value to the experimentalist working in dielectric and mechanical spectroscopy fields.

All in all, the book is informative, well balanced, well illustrated and has few errors. It is strongly recommended both for the experimentalist in the field of dielectric relaxation as well as for the advanced student of that domain.

Metabolic yearbook

The Year in Metabolism, 1975-1976. Edited by Norbert Freinkel. Pp. 353. (Plenum Medical: New York and London, 1977.) \$27.

THIS is the first of a new series of annual publications in which the previous year's developments in selected broad areas of metabolism related to human disease are reviewed. The following topics were chosen: hormone receptors, cyclic nucleotides and control of cell function; diabetes mellitus; glucagon; body fuel metabolism; obesity; lipid and protein metabolism; amino and mono amino organic acids; purine and pyrimidine metabolism; vitamins and minerals; urinary stones; the metabolic aspects of ethanol.

The topics chosen are appropriate because there is updating to be done in each case, and in some cases the authors have had to be selective within their chosen field; for example, chapter 9, "What's New—Vitamins and Minerals", deals only with vitamins C and D, although the author indicates that there may be changes in the future.

I found little of substance to criticise in this book but I am left in some doubt as to its most appropriate target. The honours student in biochemistry will find it much too clinically orientated, and the undergraduate medical student as well as almost all postgraduate medical students will find it much too detailed in a few narrow spheres. It is, in my opinion, a book for specialist metabolic physicians and medical research workers, as well as others who wish to read an up-to-date account of one of the topics covered. It will be invaluable for them.

The real test of this publication's success will be the extent to which the impetus which has brought it into being can be maintained. This implies that each chapter should be re-written for each new edition. If this can be done, it may well provide a needed intermediate between the very condensed but comprehensive publications of the *Annual Reviews* type, and several very good, well-edited and up-to-date large textbooks on the subject, with all of which it will be in competition.

obituary

Wernher von Braun

ONLY occasionally may it be claimed that a single individual has exerted a major influence on a global scale during his lifetime. For von Braun, who died in America on 16 June 1977, the claim may be justified since his work was of critical importance in war and peace throughout the turbulent years of the middle decades of this century. There was, too, a uniqueness about von Braun—that he exerted these influences in two nations divided for half of his life by two World Wars. For although his later triumphs belonged to America, who claimed his citizenship for the last 20 years of his life, he was a German by birth who created a devastating weapon of war in support of Hitler's regime.

Wernher von Braun was born in Wirsitz, Germany on 23 March 1912, the second of the three sons of Baron Magnus von Braun and Baroness Emmy von Braun (née von Quistorp). The ancestral family estates and his early environment might well have led Wernher to a traditional cultural life, but for the circumstance that his mother was an exceptional person. The Baroness was an amateur astronomer who presented Wernher with a telescope as his confirmation gift. We have von Braun's own authority for the statement that it was this event and his early reading of an article in an astronomical magazine describing an imaginary trip to the Moon which fired his determination to join the Verein für Raumschiffahrt (VfR—Society for Space Travel) in 1929. He was then a student at the Berlin Institute of Technology and the VfR, with Hermann Oberth as President, although founded only two years previously, was a thriving concern with over 500 members.

This VfR began the real German experimental work on rocket flight from the *Raketenflugplatz* at Reinickendorf on the outskirts of Berlin. Von Braun participated in the establishment of this 'rocket flying field' from which in 1931 the VfR claimed to have launched a hundred liquid-fuel rockets and made three hundred static firing tests. Altitudes of a mile were achieved but in spite of these successes the VfR almost immediately suffered from the economic depression in Germany. Their difficulties were enhanced by the increasing objections

Von Braun, arm fractured in a car accident, surrenders to the US Army in 1945. With him, L to R: Maj-Gen Walther Dornberger (Peenemünde Commander) and scientists Lt-Col Herbert Axter and Hans Lindenberg.

of the Berlin police to rocket flights within the city limits.

Ironically it was this rapid decay of the VfR which determined von Braun's future, for, in its desperation the group sought support from the German army. In the summer of 1932 a demonstration of a *Repulsor* (the liquid-fuel rocket of the successful 1931 tests) was given at the army proving grounds at Kummersdorf. This demonstration did not save the VfR—by 1933 it was bankrupt and was finally extinguished by Hitler and the Gestapo—but the army had been greatly impressed by von Braun and invited him to do the experimental work for his doctor's thesis (he graduated in 1932) on rocket combustion phenomena at Kummersdorf.

The army's rocket work was under Captain (later General) Walter Dornberger and his acquisition of von Braun was to prove an event of major significance. Two years later his rockets were reaching an altitude of 6,500 ft. and in 1937 the army rocket group of 80 personnel with von Braun as technical director moved to Peenemünde on the Baltic coast. There, under pressure

from the army to develop a missile with a range of 150 to 200 miles and capable of carrying a one ton warhead, von Braun and his team created modern rocket technology. At last in October 1942 when a test rocket reached an altitude of 50 miles and travelled 120 miles, Hitler ordered top priority for the work.

The attacks against London with the V1 (the buzz bomb) began on 12 June 1944. On 9 September 1944, three days after the Chiefs of Staff reported that all the V1 launching sites had been captured, the world's first ballistic rocket, the V2, fell on London. These attacks continued until 27 March 1945 when all the launching sites had been captured. These V1 and V2 missiles of von Braun had killed 8,938 people and injured 24,504 mainly in the London region.

For von Braun it was an immense achievement—8,000 V1's had been launched against London alone, 1,115 V2's fell on southern England and the Germans claimed another 2,000 had been launched against targets on the continent. The V2 as a ballistic missile was far in advance of anything conceivable elsewhere in the world. Weighing 12 tons at take-off the device was 40 ft long, 5.5 ft in diameter and could carry a one ton warhead 180 to 200 miles. The engine, using a turbo-pump-fed liquid oxygen and alcohol mixture and generating a sea-level thrust of 56,000 pounds worked for a minute after which the trajectory was entirely ballistic. The V2 had an inertial guidance system with two free gyroscopes, levelling pendulums and an integrating gyro-accelerometer. The rocket climbed 60–70 miles and five minutes after lift-off dropped on the target with a speed of 3,500 miles per hour.

Familiarity with contemporary rockets should not be allowed to obscure the monumental nature of von Braun's technological achievement in the development of the V2. It was a weapon which many experts in the Allied countries believed to be impossible to achieve and against which there was no defence. The effect of the V2 on the outcome of the War could well have been decisive if Hitler had not diverted priorities from Peenemünde to the Luftwaffe which curtailed von Braun's

efforts in the period from 1940 until the end of 1942. There were also internal disputes when Himmler attempted to take control of the project—an event which led to von Braun's arrest by the Gestapo and his imprisonment early in 1944 from which he was released after two weeks only by the personal intervention of Hitler.

The second phase of von Braun's career in America culminating in the development of the Saturn rockets which launched men to the moon has received great publicity and is far better documented than the remarkable episodes in 1945 surrounding his escape from Peenemünde and his surrender to the American army. In January 1945 when it was clear to him that Hitler's Reich was about to collapse, he met secretly with his top staff members to decide whether to obey the directive to stand firm at Peenemünde and fall into the hands of the advancing Russians or escape to the south and surrender to the Western Allies. The almost unanimous decision to escape was assisted by an enormous bluff. 5,000 employees and their families together with vast amounts of literature and equipment set out from Peenemünde in February 1945 in railway trains, trucks and cars blazoning prominent signs indicating a purely mythical "Project for special disposition." Carrying one of several contradictory orders implying that rocket research was to continue in the Harz mountains, the von Braun convoy forced its way through road blocks, the SS and Gestapo and eventually reached Bleicherode in the Harz mountains. 12,000 tons of equipment shipped from Peenemünde and earmarked to follow von Braun to the Harz mountains was eventually captured by the Russians in Lubeck.

At Bleicherode von Braun found himself faced with the SS General Kammler who had earlier tried to take over Peenemünde, but Kammler thought he could bargain better with the approaching Allies if he used von Braun and his team as hostages and he placed them in a prison camp at Oberammergau. Eventually von Braun managed to disperse his group into the surrounding mountains and it was from that region of the Bavarian Alps that he surrendered to the Americans early in May 1945. They had acquired one of the great technical prizes in history for, apart from the Peenemünde team, the huge underground V2 assembly plant at Niedersachswerfen was captured intact.

When he arrived at Bleicherode, von Braun hid 14 tons of documents about the Peenemünde developments in a tunnel near Dörten at the northern edge of the Harz mountains. These and large amounts of the V2 material

3 February 1958. Holding a model of the successful Explorer satellite launch vehicle. L to R: William Pickering, Director of the Jet Propulsion Laboratory; James Van Allen; von Braun.

(enough for about 100 rockets) were removed from the region only days before the Russian army moved in. Sixteen Liberty ships transported the cargo from Antwerp to New Orleans and within a year the Americans were gaining invaluable experience and commencing their upper atmosphere researches by launching the reassembled rockets from White Sands, New Mexico.

These complex and urgent movements were under the command of the US General Holger N. Toftoy, Chief of the Ordnance Technical Intelligence team in Paris. It was Toftoy who recommended that von Braun and his technical staff should be brought to the United States. On 23 July he was ordered to arrange the move but only for 100 of the staff and in early August 1945 he met von Braun at Witzenhausen to offer him a one year contract in the US under Ordnance Corps custody. Before finally leaving for the US von Braun spent two weeks in England for meetings with Sir Alwyn Crow and other members of the Ministry of Supply who had been involved in the attempts to develop British rockets during the war.

His American life began on 29 September 1945 when, with seven other members of the team, he was met at Fort Banks in Boston harbour by Col. James P. Hamill who was to be his C.O. for many years. Soon, von Braun was at Fort Bliss in El Paso, Texas. Gradually his team arrived and by February 1946 they were complete and at work on assembly and testing of the converted V2's. The first launching from White Sands, New Mexico was on 16 April 1946 and the launchings of the captured V2 rockets continued for six

years during which time the U.S. Army continued to move forward from the V2 technology under von Braun's guidance.

In 1947 von Braun was given permission to return to Bavaria to marry his 18 year old second cousin Maria Louise von Quistorp, and there are two daughters and a son of the marriage.

In October 1949 the Secretary of the Army gave formal approval for the transfer of the rocket group to the Redstone Arsenal in Huntsville, Alabama. The move in 1950 involved 500 military personnel, several hundred U.S. civilians and the technical core of von Braun and 130 members of his original Peenemünde staff. Hamill was in charge, with von Braun as director of the Guided Missile Development Division.

These were critical years for the US missile developments—spurred by the needs of the Korean War the Redstone missile was developed. First fired from Cape Canaveral in August 1953 it was the first missile to be in operational use in the US Army and was soon to play an unforeseen and dramatic part in the space research.

At that time intelligence sources found evidence that the USSR was in an advanced stage of development of an intercontinental ballistic missile (ICBM). All three US armed services were thereby spurred to vigorous development of an ICBM. The creation of the Army Ballistic Missile Agency in Huntsville under General Medaris was centered around von Braun as technical director. The Redstone rocket was upgraded and two upper stages were added to form the vehicle known as Jupiter C. The first stage

Few people can resist the temptation to stroke or fondle a kitten or cat. Unfortunately, the complex life cycle of the causal organism in toxoplasmosis, *Toxoplasma gondii*, centres on the cat family in which all stages of this coccidian occur including the highly resistant and infective oocyst.

The Wellcome ToxHA test Kit is a standardised, indirect microtitration system for the rapid detection of antibodies to *T. gondii*. Because the test detects mainly the somatic but also the cuticular antibody, it can indicate the stage of infection when used in conjunction with the Wellcome Toxoplasma fluorescent antibody test.

The Wellcome ToxHA test Kit, Code TA21

- * Utilises extracts from purified trophozoites of *T. gondii* RH strain to sensitised aldehyde-treated tanned turkey red blood cells and avoids the use of living toxoplasmas.
- * Is suitable for manual or semi-automated use.
- * The agglutination patterns can be read, in V-well plates, within 90 minutes.
- * The test is simple to perform, requires no complex equipment and, because it requires only micro-volumes of reagents, it is quite inexpensive.
- * The test cells have a consistent titre, meeting the WHO International Standard for anti-toxoplasma sera.
- * 2 x 50 test kit, lyophilised, which will remain stable at 4°C for at least one year from date of manufacture:

Test Cells/Control Cells/Positive and Negative Control Sera/
Diluent Buffer.

A GUIDE TO RADIATION PROTECTION

J. Craig Robertson

A guide for the layman faced with the problems of dealing with radioactive materials during the course of his work. Assuming no previous scientific knowledge, the book discusses, amongst other things, different types of radioactive sources and how to shield the various radiations they emit.

October 1976 £4.95

The Science Dictionaries

Three useful and up-to-date works of reference intended not only for students, teachers and researchers but also for science journalists and the general reader.

Each book is designed for easy use – entries are arranged alphabetically and defined under the most common form of term, with synonyms in brackets. S.I. units are used throughout and all entries are thoroughly cross-referenced.

A Dictionary of Life Sciences

E. A. Martin

The recent trend to treat the biological/life sciences as a whole rather than divided into separate units is reflected in this concise dictionary which brings together in one volume all the main branches of zoology and botany. Selected terms in related fields of biochemistry, endocrinology, animal behaviour and palaeontology are also included. All major plant and animal classes are fully described as well as the more important orders, and common names of animals and plants are cross-referenced to their appropriate taxonomic groups.

1977 £5.95 392pp

A Dictionary of Earth Sciences

Stella E. Stiegeler

The subjects covered here include geophysics, structural geology, geomorphology, oceanography, stratigraphy, palaeontology, sedimentology, climatology, meteorology, soil science, cartography, mineralogy, petrology and surveying. The terms defined reflect the recent modification of traditional concepts and the resulting development of terminology in the earth sciences. In soil science, for example, a new system of classification is now in use, with a completely new terminology for the soil orders.

1977 £5.95 320pp

A Dictionary of Physical Sciences

John Daintith

This book covers the main branches of physics, chemistry and astronomy – from Abbe condenser to zoom lens and zwitterion. A selection of relevant terms from the related fields of electronics, computer science and mathematics is included. Full accounts are given of the properties and uses of the chemical elements and many of their compounds. All the chemical terminology used is that recommended by the International Union of Pure and Applied Chemistry.

1977 £5.95 352pp

To order a copy of any of these books, please send £5.95 plus 50p carriage to Technical Book Services, P.O. Box 79, Maidenhead, Berkshire SL6 2EG.

was a Redstone missile lengthened to hold more propellant and the engine was modified to burn a new fuel—hydrazine, a mixture of unsymmetrical dimethylhydrazine and diethylene triamine. The second stage was a cluster of eleven solid-propellant rockets and the third stage fitting inside the ring of the second stage comprised three solid fuel rockets. Von Braun stabilised the system by spinning it rapidly during flight and on its first flight from Cape Canaveral in September 1956 this remarkable vehicle reached an altitude of 682 miles and travelled 3,400 miles.

Ironically and almost immediately the Army was ordered to concentrate on short range missiles while the control of the ICBM programme passed to the Air Force. External events, however, once more determined a different destiny for von Braun.

In 1954 he showed that it would be possible to launch an earth satellite using the Redstone rocket assemblies as in the Jupiter missile. His scheme, under the code name Project Orbitor, was considered by an advisory group under Assistant Secretary of Defence Donald A. Quarles who outvoted the idea by 7 to 2 at a meeting on 9 September 1955, in favour of Project Vanguard, an alternative proposal from the Naval Research Laboratory. The official record states that the decision was based on technical recommendations of the advisory group. More probably the phrase covers the persuasion of President Eisenhower that the military association and the constraints of the secrecy classification on the Jupiter C rocket would be harmful to the peaceful intent of the satellite project. In the event Vanguard, based on sounding rocket technology and aside from the main stream development of the U.S. military ballistic rocket, inadequately financed and with no appropriate priority, was an almost total disaster.

In the turmoil created by the success of Sputnik One on 4 October 1957 von Braun again pressed his case from Huntsville that he should be allowed to use the army's Jupiter missile to launch a satellite. Three weeks after the launching of Sputnik he was given three and a half million dollars with a target date of 30 January 1958. Once more he triumphed—on 31 January the Jupiter rocket placed Explorer 1, the first American satellite in Earth orbit which within a few days discovered the zones of trapped particles around the Earth (the van Allen zones). The decade of intense technological rivalry between the US and USSR following these events would have borne a radically different aspect if von Braun's advice had been followed in 1955.

After these events the Eisenhower administration took immediate action to create a unified US space effort. Following the advice of a committee under James R. Killian steps were taken to create a strong civilian-orientated agency to direct the manned and unmanned exploration of space. The National Aeronautics and Space Act became law on 29 July 1958. Successively this National Aeronautics and Space Administration absorbed the 8,000-strong National Advisory Committee for Aeronautics, the Vanguard and NRL groups, the 2,800 staff of the Jet Propulsion Laboratory of CalTech and then in January 1960, President Eisenhower decreed that the vital army group, with 4,600 personnel under von Braun should be transferred from army to NASA control. On 1 July 1960 the transfer was effected when the President personally visited and dedicated the facility as the George C. Marshall Space Flight Center with von Braun as director.

Four years earlier von Braun had begun studies of rockets which would be far more powerful than the Redstone combinations. He knew that the rockets required for intercontinental missiles would never provide the thrust required to place man into space. In August 1958 he already had approval to develop a multiple Redstone/Jupiter combination with a thrust of 1.5 million pounds, and by the time of his absorption into NASA he had a priority rating for the development of vehicle known as Saturn 1. In October 1961 this 162 ft long carrier rocket weighing a million pounds had its flawless test launching from Cape Canaveral. By January 1964 a 3,700 pound test payload was placed in orbit. Thereafter von Braun progressed majestically and incredibly to the targets of the Apollo programme and to the fulfilment of his vision.

These early Saturn vehicles were mere stages towards the mammoth Saturn 5, the development of which was approved by NASA in January 1962. Standing 364 ft high, Saturn 5 weighed over six million pounds and could send 47 tons of payload to the Moon or place 140 tons in Earth orbit. The landing of Armstrong and Aldrin on the Moon in July 1969 was an operation of extraordinary complexity; an immense collaborative enterprise which von Braun and the Huntsville team made possible by designing this multi-million pound thrust rocket. From assembly to the count-down the monitoring system alone needed 10 miles of tape storing over 2.5 million words.

Von Braun witnessed the fulfilment of a youthful dream in his fifty-eighth year. No longer did it seem technical fiction that he wanted to proceed even

further along this path. He had designs to get man even further into space. First he would have strapped on solid rocket motors to the first stage of Saturn 5, then to get the men to Mars he planned to replace the existing liquid hydrogen-oxygen third stage by a nuclear engine. But this remained a dream; NASA was forced to cut the space programme and within a few years of the climax of Apollo 11, von Braun had the chagrin of witnessing the dismantling of the facilities and the dispersal of the men who had made Saturn a reality.

In 1970 von Braun was made Deputy Associate Administrator for Plans in NASA, an office which he held until his retirement at the age of 60 two years later. He then joined Fairchild Industries as Vice President for Engineering and Development but became ill with cancer and retired finally a few months before his death.

Von Braun was an extraordinary symbol of the age. His vision was of a nature which the establishment looked upon as science fiction but by single-minded persistence he astonished the world by succeeding through the labyrinth of war and peace, first as a German and then as an American citizen. Although von Braun was granted American citizenship in 1955 and rescued the Americans from their despair in the face of the Soviet Sputnik, there were those who could not forget that he laboured for the Nazis. But for von Braun the transformation was complete. He built his rockets to get men away from the earth—his imprisonment during the Peenemünde era resulted from an unwise remark that the V2 would help towards space travel—and he succeeded.

Bernard Lovell

D. W. Holder

At the time of his death on 18 April 1977, Professor Holder had been Head of the Department of Engineering Science at Oxford for close on sixteen years. In that time the laboratory had expanded at both the undergraduate and postgraduate level and much of the planning for this growth stemmed from his own initiatives.

He was educated at Imperial College in the Department of Civil Engineering between 1941 and 1943 and subsequently in the Aeronautics Department under Sir Leonard Bairstow. After graduating he immediately joined the Ministry of Aircraft Production at the Aircraft and Armament Experimental Establishment at Boscombe Down but soon transferred to the Aero-

dynamics Division at the National Physical Laboratory where he remained until 1961. His promotion from the junior grades to Deputy Chief Scientific Officer in 1957 was rapid and his career at the NPL spanned some of the most dramatic changes seen in aeronautics.

At the end of World War II, little was known about the behaviour of aircraft at transonic and supersonic speeds but the next decade was to change all that and Douglas Holder played an important role from the outset. The first problem was to design and build the wind tunnels which would enable the aerodynamic phenomena to be investigated. The Aerodynamics Division chose to use induced flow tunnels and a series of these ranging from the original pilot model 9 inches by 3 inches in cross section to 36 inches by 14 inches was constructed.

Before 1949 research on flow at Mach numbers close to unity had been impossible because of the reflection of the normal shock from the tunnel wall. Extensive studies of slotted walls were conducted in the UK and the USA and Holder's group at NPL made substantial contributions to this new technique which could eliminate tunnel interference effects. In addition to this work on tunnel design he made, with Gadd and Pearcey, important advances in shock wave boundary layer interaction and aerofoil design so that the division as a whole established an enviable international reputation.

Following closely on this pioneering research on transonic and supersonic aerodynamics Holder next led the development of a series of shock and wind tunnels for the study of flight at hypersonic speeds, i.e. above about Mach 7. Completely new techniques were needed to drive such facilities and Holder, now head of all high speed aerodynamics at NPL, took a major role in planning and designing these devices. The flow durations in shock tubes and shock tunnels range from tens of microseconds to a few milliseconds but Holder was equally at home in this new field. He had very early demonstrated a highly developed skill in wind tunnel design and had the ability, which may be the mark of the true engineer, to make rapid estimates of all the important design parameters for a new facility. Throughout this period he published, as he had always done, widely, and some of his papers are classics of their kind.

In 1961 he was invited to take the Chair of Engineering Science at Oxford to succeed Thom who was then retiring, and became at 37 the fourth holder of that post. The early sixties saw in Oxford, as in the UK as a whole, a rapid expansion of university engineer-

ing departments and under Thom a major development had been initiated. Holder took over this work and guided it through to completion. Although he continued to take a keen interest in fluid dynamics he also saw the importance of maintaining and extending a broad base of knowledge and there are now two new chairs in structures and electricity, largely due to his foresight and persistence.

His long association with aeronautics at the NPL made him an obvious choice as a consultant for industry and government and he was also much in demand in educational establishments. He was elected FRS in 1962 and served on many of its committees as well as its Council between 1969 and 1971. His wide range of activities outside Oxford constantly suggested new lines of research and development and together with Professor R. B. Duthie he established in Oxford a centre for orthopaedic engineering and encouraged work in physiological fluid dynamics.

Outside of Oxford his government advisory work was at the highest level and must remain obscured by confidentiality although he will be remembered for his chairmanship of the enquiry into Precision Approach Radar following the Gatwick disaster in 1969 and later, in 1971, his involvement at ministerial level in the technical decisions on the future of the RB-211 engine.

By nature he was reserved and the extent of his influence in both aeronautics research and engineering education is a testimony more to his patient and persuasive skills than to any justifiable forcefulness in argument. He was an exceptionally able administrator and dealt with what would appear a crippling work load with quiet efficiency. He was always ready to listen to his staff and research students and to encourage them to pursue new lines of investigation and he was generous to a fault to those who were in difficulties, although few around him would be aware of his very personal interventions. In this respect he was particularly effective on the University Staff Committee where he will long be remembered for his patient and skilful administration.

In his views of the part that universities should play in the industrial life of the country he was ahead of his contemporaries and with such wide experience and extensive contacts he often put his finger on promising lines of new work long before they were apparent to others. There are, alas, only a few of his calibre and he will be sadly missed in both university and industrial bodies.

D. L. Schultz

Yves Guitton

PROFESSOR YVES GUITTON died on 6 July 1977 in Perpignan (France) at the age of 46. He leaves a wife and two sons. Head of the Laboratory of Plant Physiology, he was also chairman of the University Group for the Biology of Development and Parasitology and Vice-president of the University of Perpignan.

With a wide-ranging scientific background, involving organic chemistry, nuclear energy research and microbiology, he entered plant physiology and biochemistry because he felt the development of this field to be essential for the future. His doctoral thesis was devoted to the metabolism of arginine during the germination of *Pinus*, and his contribution to the study of amino acids and nitrogenous substances was invaluable to French biochemistry.

In 1966 he was appointed to the newly-created University of Perpignan, addressing himself to a problem which intrigued him: the role of nucleic acids in developmental processes. Arriving alone in his new laboratory, geographically isolated from the scientific community, Professor Guitton nevertheless created within ten years a laboratory equipped for all techniques of molecular biology. The research team which he built up is a leading group in French physiology, collaborating with others both at home and abroad.

His recent contributions concern the metabolism of mRNA during the first hours of seed germination, mRNA stability and development-related changes in chromatin structure and composition. With his collaborators he was the author of around fifty publications in French and international journals.

In addition to his brilliant scientific career he involved himself with equal enthusiasm in his outside interests. An excellent footballer in his youth, he turned his attention to tennis after a serious accident, rapidly reaching a high standard. Many will remember his arrival at scientific conferences complete with tennis racquet, looking for partners among his American and British colleagues. In politics he was a highly active member of the Socialist party, deeply involved in the problems of his city.

For those who knew him Yves Guitton will be remembered not only for his exceptional achievements, but perhaps even more for his enthusiastic approach to all which concerned him and his warmth and friendliness in any company. His premature loss will be deeply regretted by his many friends in the scientific community and in his city. Michel Delseny

Protection for the non-academic student

MOST people's image of the educational system is of a pyramid structure, with a broad base up to the age of about 16 and then a progressively narrowing superstructure as more and more students peel off into employment, until the giddy and narrow heights of the doctorate are reached. In a recent report the Organisation for Economic Cooperation and Development (OECD) asks some profound questions about the suitability of this structure for the present day (*Selection and Certification in Education and Employment*, OECD, 2 rue André-Pascal, Paris). One of the most interesting questions concerns the so called terminal/transfer dilemma, and has a particular relevance in a period when secondary schools are being required to accept children of a very wide range of abilities into so-called comprehensive education.

The OECD points out that such schools have to combine two functions previously fulfilled on separate tracks: that of preparing students to leave the educational system for employment, and that of training and most often selecting students for transfer to the next higher level. In practically all cases, claims the OECD, the result of this uneasy merger is that curricula and assessment practices are geared primarily to meet the needs of those who will move up, even if this number is actually a minority. The higher levels of the pyramid exert a strong influence on those beneath. It might be added that in many universities the same pattern exists for the sciences: the need to select and

train the postgraduate unduly influences the undergraduate curriculum.

At the secondary level of education the move towards comprehensive schools has clearly been seen by its proponents as a move towards greater equality of opportunity and freedom to find one's own level. If however, comprehensive schools develop in the way that the OECD describes, they will only tend to emphasise failure. Those for whom such a school was never other than their last base before getting a job will find themselves poor relations alongside those with obvious university aspirations who are catered for by examinations and school curricula with the word 'university' written all over them.

If the so-called holistic structure of an educational system acts to the disadvantage of those with 'mere' manual and technical skills, does the alternative 'aggregative' model, with tertiary education pursued in a much more diverse way, work any better? Certainly it could help to break a narrow academic grip on schools, but maybe at the high cost of fragmented tertiary courses, much poorer staff-student relationships and a general lack of direction in many students' development.

Is there a middle path, that maintains the best of academic traditions without casting out the non-academic student into outer darkness? We must find an answer in the next few years; the OECD report could be a valuable basis for discussion. □

Read all about something like it

"MANY killed in earthquake . . . where's the pun in that?" a sub-editor on The Guardian is supposed, in newspaper mythology, to have said whilst appraising headlines. 'Buy now while stocks last' ran the headline to a leader in The Guardian last Saturday; true to form the content of the leader was not about declining resources or exceptional bargains—it was another little poke at the quaint language that specialists use. Only a few weeks ago The Guardian was pointing out the intelligibility of New Society as opposed to the opacity of New Scientist and Nature. Now it returns to the fray to renounce its faith even in the accessibility of the social sciences on the basis of an advertisement in New Society for a book *An Eclectic Approach to Primal Integration*, and it snips a highly technical sentence on adenylate cyclase out of last week's New Scientist to reassure readers that we scientists are still at it.

No doubt our colleagues on the New Scientist know how to defend themselves against these outrages, but for our part we simply say that at least our customers know what they are getting. Anyone who picks up an article

entitled 'Analgesic activity of lipotropic C fragment depends on carboxyl terminal tetrapeptide' can be under no illusions about what they are in for, whereas readers of The Guardian may have to search for a serious article on Indian corruption under a heading such as 'Currying Favour'. Nor is ambiguity restricted to The Guardian. Every evening as we walk wearily from office to station we are assailed by placards for the evening newspapers proclaiming 'London-bound train crashes', only to discover that a freight train from Glasgow has run off the rails outside Preston.

Our enthusiasm for this theme of misrepresentation having been raised, we were just about to go on in the same vein to wonder how many horticulturalists had bought John Betjeman's *A Few Late Chrysanthemums* by mistake, how many glaciologists Margaret Drabble's *The Ice Age* and so on when an uneasy feeling crept over us. After all in the office we do get a steady stream of offers of wildlife pictures. And we get the occasional phone call asking if we have the address of the World Nudist Federation. □

Of time and the energy wars

In another of an occasional series, Alvin M. Weinberg, Director of the Institute for Energy Analysis at Oak Ridge, Tennessee, comments on a difficult trade-off

QUANTUM mechanics tells us that energy and time are conjugate variables. I am therefore much bemused these days by an observation pointed out to me by a young Swiss physicist, Daniel Spreng, that in a certain social sense energy and time are conjugates. What Dr Spreng means by this is simply that man expends energy in order to save time; moreover, when given the choice, he usually chooses to save time over saving energy. (To be more accurate, it is availability rather than energy that is usually meant in these contexts).

This surely was the case during man's early civilisation. Domestic animals did the job quicker, and slaves were acquired because they were a source of intelligent energy. The slave-owner therefore had more freedom of choice in using time than did the peasant who had to work his field himself. And each technological achievement (at least until the advent of information technology) represented such a trade-off: the industrial revolution, the transportation revolution, the agricultural revolution—always it was man in a hurry ready to spend more energy in order to save time.

Actually this exchange of energy for time has a basis in thermodynamics, despite the well-known fact that thermodynamics never treats time explicitly. In thermodynamics we learn that the minimum free energy is expended when a process, like desalting, is performed reversibly. A reversible process, however, is usually considered to require an infinite amount of time; if we wish to save time, we must expend more energy since the process will then be performed irreversibly. Thus the minimum amount of work required to desalt 1,000 gallons of seawater is 3 kWh; the actual amount used in a practical desalting device is ten or more times higher than this.

Heat transfer processes can be performed *reversibly* in a finite time if the apparatus, particularly the heat transfer surface, is sufficiently large. In that case the temperature drops approach zero, and reversibility is achieved. But we must remember that the total energy required to conduct a process is actually the sum of two energies: the usual energy which is transferred from one body to another; and the energy that went into constructing the apparatus. Ordinarily we ignore the latter. But if the apparatus becomes very large we ought not to ignore this since the energy that went into making the apparatus—the mining and refining of the metal, its fabrication, its transport—becomes very large. Thus the total energy goes through a minimum as the degree of irreversibility diminishes. To perform a task in a finite time requires more energy than to perform it in a longer time, either because we do it irreversibly or because to do it reversibly requires a very large apparatus that itself embodies a great deal of energy.

Though I am bemused by the fact that time and energy can be regarded as conjugates, I do not put this forth as a magical talisman for guiding our course in the great energy debate, but simply as an antidote for the view that thermodynamics can guide energy policy better than can the evolving values of our society, particularly as embodied in economics. This view seems to be promulgated, especially in the United States, by Barry Commoner and Amory Lovins, to mention the most notable. They assert, with truth, that in principle we can save energy if we do a better job of matching the quality of the heat source with the quality of the heat required to achieve a given end. If water is wanted at 70 °C, why use a flame with a temperature of 1,000 °C as the heat source? And in two widely read

Camera Press

Time savers, or energy wasters?

articles, Commoner's "The Poverty of Power", which appeared in the *New Yorker* and then as a book, and Lovins' "Energy Strategy: The Road Not Taken?" which appeared in, of all places, *Foreign Affairs*, much was made of maximising this 'second law efficiency'. Indeed, the lesson thermodynamics teaches us for energy policy, according to Commoner and to Lovins, is mainly that we must maximise second law efficiency: in so doing we will save energy and create the good, that is, decentralised society, not to say eliminate nuclear energy.

But all this is so one dimensional. To be sure energy is a finite good, and we suffer from a shortage of it. But there are other goods that are finite, and of these I would consider time to be the most fundamental. This, I suppose, is one of the prices we pay for our knowledge of our mortality: we value time because we know it is limited, and we will do much to save it and to expand our choices in using it. If the underlying trade-off is between energy and time, then we mislead if we try to use thermodynamics as a primary guide to energy policy since thermodynamics gives no value to time: it is prepared to speak of processes that are infinitely slow, that ignore man's mortality.

There are those who argue that we have passed the point where energy can be exchanged for time. For example, S. Linder in *The Harried Leisure Classes* points out that our energy-intensive technologies themselves rob us of time: to maintain our gadgets, to commute, to listen to the semantic drivel that our new technologies impose upon us. And I cannot deny the merit of Linder's thesis: the Leisure Class is harried.

Yet who is to judge whether the trade-off between energy and time is to favour energy or time—the energy revolutionaries such as Commoner and Lovins, or the rest of us? We are short of energy, but we are also short of other things, like time. A free society allows each of us to make the choice, to allocate as we each decide. Economics, in the broadest sense, integrates all these trade-offs and judgments—it allows us to weigh time against energy, or for that matter, any other good against energy. I would hope the energy revolutionaries could be persuaded to be a little less revolutionary and not reject these homely truisms of engineering economics for a world they would impose on us with their emphasis on thermodynamic analysis. □

Planning Antarctica's future

The thirteen signatories to the Antarctic Treaty met in London earlier this month. **Paul Cheeseright** reports

IN THE face of increasing international economic pressures, the Antarctic Treaty is on the verge of substantial change, which could dilute, at least to some extent, the environmental stringencies practised to date by the signatory powers. The essential problem is how to control an area without having the recognised forms of sovereign jurisdiction.

For three weeks in London the thirteen consultative powers, as the signatories like to call themselves, tried to come to terms with the problem of finding regimes for the control of marine and mineral resources, while at the same time preserving the non-political approach which has hitherto dominated their scientific work. Inevitably their success has been only partial.

This inevitability is the direct result of the framework in which the Treaty powers had to work. There are thirteen of them: Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, Poland, South Africa, Britain, the USA and the USSR. They make an oddly variegated bunch of states, having either geographical, historical, political or scientific links with Antarctica.

The Treaty which binds them was signed in 1958 and came into effect in 1961. Its effect has been to make the most inhospitable continent in the world a gigantic laboratory, where the work of one was subject to the inspection of all in a demilitarised nuclear-free zone reserved for peaceful purposes. "The question of man's impact on the Antarctic environment" is, the Treaty powers say, "a subject which subsumes all the main preoccupations of the Antarctic Treaty powers with regard to the area".

The early years of the Treaty's existence provoked no problems. The area was out of the way. The scientific work was expensive and only the powers involved were interested in making provision for it. But in 1969 questions were being asked in the New Zealand parliament about the mineral resources of the region. The seeds of difficulties were being sown.

There were two reasons for this. The first was that the Treaty itself made no mention of resources in the area and what to do about them. The second was that the Treaty effectively froze all territorial claims to the area for thirty years. It was at least partly in order to lay the claims to rest for a generation that the Treaty was signed

in the first place.

Seven Treaty signatories have claims: Argentina, Australia, Chile, France, New Zealand, Norway and Britain. But these claims are not recognised by the other signatories and are not accepted even among the claimant powers, because the claims of Argentina, Chile and Britain overlap. In addition some 15% of the Antarctic land mass is unclaimed. The danger of the mineral resources problem was that it could bring out into the open the territorial claims, because in the event of mineral exploration or exploitation there would need to be some jurisdiction over the activity.

Rights questioned

In recent years however, the rights of the Antarctic Treaty powers to define even loose methods of control of the area have been questioned. The United Nations Law of the Sea Conference embraced the concept that the oceans were the heritage of mankind. There is no reason, some Third World powers have argued, why the same concept should not be applied to Antarctica.

In the event the problem of mineral resources has not had quite the same urgency as marine living resources. The latter involve primarily the krill, a crustacean seen by some scientists as a major untapped source of protein which could be harvested in sufficient quantities to double the world's annual fishing catch.

The depletion of the region's whale stocks has led to an increase in krill stocks, pointing to the role of the

creature in the ecosystem of the southern oceans. But detailed knowledge of the ecological interaction of the krill and other Antarctic marine species has not yet been accumulated. It is not even known whether the Antarctic contains one or numerous distinct krill populations.

Nevertheless the proliferation of the krill and its ready exploitation have already attracted the attention of West Germany, which has reported catches of 40 tonnes an hour, the USSR, Japan, Chile and Poland. It has also been the subject of survey by the Food and Agricultural Organisation (FAO).

The implications of all this for the Antarctic Treaty powers at the London meeting were serious. If environmental damage was to be prevented then it was necessary to find a regime of conservation, but the regime would have to be voluntary. Unless national territorial claims with 200 mile economic zones were to be recognised in defiance of the Treaty and of some of its signatories, there could be no policing. At the same time the lack of any internationally accepted system of authority meant that any nation could move its fishing vessels into the area.

The Treaty powers are planning a conservation regime, which they hope will be ready for signature at the end of next year. Such a regime will embrace several principles, they decided. In the first place it will include the "rational use" of resources, so harvesting is not prohibited. In the second place they are mainly concerned with the seas south of latitude 60°S.

The third principle is that the regime would exclude catch allocations. At the same time, however, it could involve a total catch figure. It is not clear how it is possible to have the latter without involving the former.

The fourth principle is extension of the freezing of territorial claims into the conservation regime. The effect of

Krill, caught on the wrong side of a whale

this is to ensure the rights of free access into the southern waters adjacent to the continental landmass. While this constitutes a leap over a major political hurdle and ensures a degree of order in the affairs of the continent, concomitantly it means looser control.

But the way has been opened for widening the international acceptance of the Treaty. The powers are considering inviting countries like West Germany to take part in the drawing up of a conservation regime, and international organisations like FAO could send observers.

In general the Treaty powers are anxious that any nation which is active in the area should accede, so that practical answers may be provided to practical questions. The Treaty is not closed, but the powers remain concerned about the possibilities of hegemony by an international organisation which might diffuse authority still further and act not as a spur to action but as a block.

Interim guidelines

In the meantime, pending a definitive conservation regime for marine living resources, interim guidelines have been established. But they do not go beyond commitments to cooperate in research, coordinate shipping programmes and the exchange of catch statistics. The

guidelines are accompanied by an acceptance of the need not to harvest the resources to the extent that there will be depletion.

In common with the principle adopted for marine living resources, control of the continent's mineral resources will not affect the position on territorial claims. But the Treaty powers have made their strongest commitment so far not to engage in mineral resource exploration until a regime of control has been established. This they intend to work towards. That said, however, there is no theoretical reason why a company should not start drilling in the area.

But this is not likely. Mining companies have already pointed to the distance of Antarctica from the world markets, the easier access available to resources in more hospitable climates and the expense of coming to terms with land covered by an ice sheet. The reservations of the companies are also held by experts from the Treaty powers. Their discussions and conclusions have taken a good deal of the pressure away from the need to reach quick solutions on control.

It is thought that it will take at least five years to amass the scientific and technical data necessary to provide a foundation for exploration and subsequent exploitation if conditions are to

be found which safeguard the continental environment. Exploratory drilling itself might take ten years. In short the possibility of exploiting mineral resources is at least 15 years away, and probably more like 25.

This assumes that the continent has hydrocarbon and other mineral resources economically worth exploiting. This is not proven. Geological history indicates the possibility, but so far only traces of mineralisation have been found on land, although unmetamorphosed tertiary sediments, often associated with oil and gas, have been discovered in areas offshore.

There is no technology available for oil production all the year round in Antarctica. The concepts for self-contained installations on the seabed exist but that is all. On land there is no technology available for drilling through the ice shelf.

Meanwhile the Treaty powers have the immediate problem of ensuring that the information they collect is made available to all who need it. The continent is vital within the international meteorological system, but the powers have discovered that only 25% of their observations ever reach the world system. Somewhere between the Antarctic research stations, the global telecommunications system and the world weather watch, the rest evaporates. □

Ninety days and more

As the Windscale inquiry draws to an end, Eben Wilson sums up progress

THE Windscale inquiry has become an institution—the British democratic tradition gone wild in the interest of a public debate about nuclear power. In its ninety days, independent and government scientists from throughout Britain and abroad have for the first time been disagreeing and airing their uncertainties in public, while wrestling with the thorny problem of the close links between nuclear power development as an energy option and its social and political consequences for the future.

The inquiry has taken over a civic hall of 1960s' architectural utility in Whitehaven, a small town perched almost inaccessibly on the Irish Sea coast to the West of England's Lake District, eleven miles from Windscale. Inside one large room, the inquiry inspector, Mr Justice Parker, a high court judge, and his two assessors, Sir Frank Warner and Sir Edward Pochin, sit trapped at a green baize table among a pile of papers. They look out

on five rows of lawyers, scientists and environmentalists who hide behind their green baize tables loaded with documents, articles and studies on nuclear power.

Out of that sea of paper a pile of daily transcripts now four feet high has appeared. Many say these will become an historic document, the quintessential reference work for the international nuclear debate.

Although the inquiry is specifically trying to decide on a planning application to build an oxide fuel reprocessing plant (THORP) alongside Britain's present Magnox reprocessing facilities at Windscale, it has become the platform for discussions on Britain's future energy options. Ranged against British Nuclear Fuels (BNFL), who own the present plant, is an array of pressure groups and individuals, from the established Friends of the Earth (FOE) to local housewives worried about their children.

The Friends of the Earth have waged

war on the economic case for reprocessing and have convinced the inquiry that the British taxpayer will have to pay somewhere between £300 million and £500 million to recycle spent oxide fuel from Britain's advanced gas cooled reactors (AGR). The exact figure depends on where the price of uranium lies between \$30 per pound and \$100 per pound, and a notional price for plutonium above £90,000 per tonne. BNFL estimate an ex-works price for recycled fuel of £260,000 per tonne or above depending on whether permission is given for a 1,200 tonne per year plant with capacity for foreign reprocessing contracts, or a 600 tonne a year plant only for British fuel.

The FOE alternative consists of importing uranium for fuel, storing fuel elements on a long term basis and abandoning reprocessing. They have asked for a ten-year delay to THORP while long term storage is researched. If this fails, they say, the delay would at least give time to try to evolve safeguards against plutonium proliferation.

British Nuclear Fuels have an unhappy history of Magnox fuel elements deteriorating in their cooling ponds at Windscale and have revealed that AGR fuel, still less than ten years old, is already showing signs of corrosion.

They view reprocessing as good waste management and point out that against the cost of reprocessing has to be put the cost of fuel storage, which nobody knows, and that storage itself does not guarantee that fuel elements will not eventually have to be dealt with either by glassification (at £450,000 per tonne), or even reprocessing to prepare fuel for glassification.

Scientific struggles

The real scientific struggle has been over the level of discharges from Windscale into the Irish Sea. These contain long-lived α -emitters, ^{239}Pu and ^{241}Am and shorter lived isotopes of ^{137}Cs .

Hours of evidence and reams of paper have shown disturbing inadequacies in the research done by the Ministry of Agriculture, Fisheries and Food (MAFF) and the Fisheries Radiological Laboratory (FRL) into transuranic marine pathways back to man's environment. The Isle of Man government produced Dr Vaughan Bowen, an expert in marine pollution from America, who castigated the FRL for its methods of measuring silt movements and biological pathways. Dr Brian Wyne for the Network for Nuclear Concern and a research lecturer at Lancaster University, cross-examined both MAFF and FRL at length on the critical group method of evaluating derived working limits for the consumption of contaminated organisms. Cod, muscles, porphyra (an edible seaweed), silt and more have been metaphorically and literally dissected to examine possible synergistic effects of low level contamination or the possibility of biological systems concentrating transuranics.

The result of the public analysis has been a mixture of scientific humility and confusion, and human arrogance and anger, each coming from both objectors and government scientists. Researchers using the transcripts after the inquiry will find long lists of documents showing the present confusion over the effects of low level radiation and the concept of a threshold for radiation below which humans are not affected.

Much evidence has been presented attacking the present International Commission on Radiological Protection (ICRP) limits. Dr Sadao Ichikawa from the Laboratory of Genetics at Kyoto University, Japan, in particular, presented disturbing evidence on the long term genetic effects of low level radiation.

The weight of all the technical evidence threatened to swamp the inquiry in its sixteenth week in a shower of facts when Justice Parker admitted that he and his assessors were falling behind under a deluge of documents.

Awaiting assessment: the Windscale plant

Making assessment: Warner, Pochin, Parker

Equally, however, it has given the inquiry a certain authority, so that when Thomas B. Stoel from the National Resources Defense Council (NRDC) in Washington, DC, came to suggest that a full environmental impact study should be done for Windscale, Justice Parker was able to wonder aloud and a little wearily what he had been doing for the past 74 days.

The overall impression of the discharge arguments has not been that BNFL are pumping death every day into the sea, but rather that nobody yet really knows what happens to the radiopathogens once they get into the silt and marine food chains. Both Dr Wynne and Dr Bowen have pleaded that independent bodies be funded to allow a plurality of research into radiation hazards.

Justice Parker could be forgiven for sighing and wondering what all this has to do with building a reprocessing plant now. He is known to favour risk comparisons with other industries and a practical approach to hazards. He has acted swiftly on the more alarmist claims made at the inquiry. The Lake District's water has been tested for tritium, air sampling is being done at Ravenglass a few miles from Windscale, and twenty local volunteers are

undergoing whole-body monitoring tests at the plant. The scientific groups on both sides of this application have agreed that the tests will prove nothing—an ironic consensus, as witnesses have usually retreated behind the armour plating of “not enough information” when under pressure.

The Oxford Political Ecology Research Group (PERG) faced the problem of getting enough information when they attempted to calculate the consequences of an accident at Windscale. A computer programme was provided by the Safety and Reliability Directorate, but agreement could not be reached on a possible mechanism for an accident that would provide the inputs to the programme.

Stunning realism

Justice Parker has gained a reputation for realism. He stunned the objecting groups at the beginning of July by declaring that alternative energy strategies in place of nuclear power would have to be presented showing “how and when and to what extent, and at what cost the energy gap can be filled”.

Strangely perhaps, the presentation of alternative energy sources has been made by ex-motorway campaigner, John Tyme. Stephen Salter of Edin-

burgh University explained wave-power systems, prophesying that the first string of 50 "nodding ducks" will be in the sea off the north of Scotland by 1984. Dr Peter Musgrove of Reading University put four hundred windmills into the Wash in the 1990s to produce around a quarter of Britain's energy demand at a price not far above the cost of coal now. His figures are becoming firmer every year. Solar power, biomass, seabed organic sediment fluidisation, combined heat and power, fluidised bed combustion were all at different stages into the future with corresponding scarcity of operating costings. But more traditional benign systems like water power, tidal power, and of course conservation were available options today.

The problem is money, either for research or first generation operating plants. All the witnesses giving evidence on soft energy paths claimed Britain was being slow in investigating alternative options. Amory Lovins' book *Soft Energy Paths*, which appeared during the inquiry, rapidly became the 'bible' on the way and the will for a move towards these options.

Time-scale has been Justice Parker's concern. John Tyme's trump card has been Yorkshire miners' leader Arthur Scargill, presenting the case for bridging the gap before a soft energy future with a huge expansion of the coal industry. This almost worked, although BNFL did a pretty savage job in cross-examination on both the productivity record and safety record of the coal industry in comparison with the nuclear industry.

The energy establishment represented by the Central Electricity Generating Board (CEGB), the South of Scotland Electricity Board (SSEB) and the Department of Energy itself faced a barrage of criticism from objectors. Surplus generating capacity, the downturn in energy demand since the oil crisis, and a radical change in

energy coefficients of new innovations were cited as proof that present energy demand forecasts are far too high. In particular, Dr Peter Chapman from the Open University Energy Research Group tied up the present view of energy relying on supply needs, with the need to change to a soft energy scenario based on energy income.

The nuclear industry is of course cursed with one emotive argument above all—the Bomb. The inquiry has not denied that nuclear warfare is a terrifying prospect. But British Nuclear Fuels has been at pains to deny that it is a conceivable prospect for future generations living with large quantities of plutonium resulting from reprocessing. Britain will be custodian to fifty tons of plutonium by the end of the century if THORP goes ahead. Five tons would fuel the first commercial fast reactor CFR 1. Throughout the inquiry the shadow of safeguards and security has been cast over the proceedings.

The fall-out from this has gone in three directions—towards terrorism, international nuclear diplomacy and civil liberties. BNFL thought they had squashed terrorism by their insistence that "measures" could be taken to prevent theft of plutonium. "Spiking" (making it radioactive), only returning it on contract as refabricated fuel, and the sheer difficulty of making a device that explodes rather than produces a large criticality excursion, are enough of a deterrent to BNFL. They add that there are easier ways to achieve political ends without dabbling in radioactive materials.

But BNFL's confidence was rudely shaken by two American witnesses. Professor Arnold Wohlstetter from the University of Chicago has explained to the inquiry that a nuclear device has been exploded using reactor-grade plutonium in the USA. Tom Cochran, again from the NRDC in Washington, DC, presented evidence outlining the

numbers needed for an armed raid on a nuclear plant (around nine outside and three inside.)

Avoiding proliferation

FOE have maintained a consistent line on the international threat of plutonium proliferation. They see as inevitable the political pressures for reprocessing contracts that specify return of plutonium after a certain period. The motivating force of Walt Patterson, their scientific adviser, has been proliferation, with a specific image of a world where shipments of plutonium will become familiar, leaving contempt for safeguards to provide the inevitable disaster.

Positive suggestions to avoid proliferation have been made by Professor Joseph Rotblat from London University. He favours an international bank for buying in, storing, and allocating nuclear materials to establish the nuclear industry as a global enterprise. Research into storage options, reprocessing and the fast breeder would all be done under international licence. Reprocessing would be abandoned until proved essential.

Whatever the solution to proliferation, the attempt is to avoid the Orwellian 'plutonium economy'. Both the National Council for Civil Liberties and Justice made pleas that future generations would not be committed to a life of surveillance, power parks guarded by automatic weapon carrying police, and hunts for subversives.

By holding a mental map of all this in his head, Justice Parker has gained immense respect for the intellectual feat he is attempting. The weight of evidence is with the objectors, there being more of them, but he will be typically concerned with common sense applied to reprocessing now in Britain.

In retrospect Whitehaven has been an essential part of the spectacle. Inquiry faithfuls staying in enclaves throughout the town have been indulging in increasingly frenetic energy outlets as time goes on. Beach barbecues, pony-trekking, and a treasure hunt, where a vital clue was missing leaving ten stranded inquirers tearing around the Cumbrian countryside in complete confusion, have added colour to the interminable days of evidence and cross-examination.

Foreign visitors comment on the lack of armed police at the doors and the politesse of the participants. Perhaps it's one of the problems of the inquiry that the British will never see something as *that* important. The feeling now as summing up begins is "we wish the end of term party would come". But although the work is ending for some, for Justice Parker it is just beginning. □

Windscale's head-end plant: no longer working, it has reprocessed oxide fuel

PROFILE

Chris Sherwell on Professor Geoffrey Allen

SRC's new head, old hand

GEOFFREY ALLEN heads a 400-strong organisation that wields a budget of over £125 million and influences the fate of the great majority of Britain's basic researchers. He is not new to its workings. But he is new to his post. He took over from Sir Sam Edwards as chairman of the Science Research Council at the beginning of the month.

The job demands practical experience of research and of administration and, if possible, of the 'real world' outside both. It also demands more than a little political nous. An erratic economy makes consistent support for Britain's research effort hard to achieve. To fight for money on behalf of scientists at large, and then dispense it on behalf of the community at large, is just as difficult.

So how did Professor Allen come to it? Under the British system which chooses to recruit through the grapevine, he wasn't the first man approached. But he is realistic about this. He accepts the system and says he has used it himself. Equally, he'd be happy if jobs like his were advertised—provided the minister concerned (at Education and Science) was not constrained by the list of applicants. He is also sure that if the job had been advertised, he wouldn't have applied for it.

He is admirably qualified, of course: a polymer scientist of 48 elected last year to the Royal Society, he has SRC and industry (especially ICI) connections going back many years. The problem was that he had recently taken up the chair of chemical technology at Imperial College, and was starting a research group there; he couldn't easily ask for a 4-year leave of absence. When the approach came, however, the decision wasn't difficult for him personally; rather, it was simply a matter of working out the possibilities and reaching agreement with Sir Brian Flowers at Imperial and with the Department of Education and Science.

What Allen calls his pragmatic view of life and work comes, he says, from his background. He was born in the Derby mining town of Clay Cross, the son of an engine driver. A Methodist Sunday School teacher taught him self-discipline. And a donnish ex-Cambridge maths teacher at grammar school inspired his love for science. He sees nothing significant in the fact that he has since

'made good'. "The good thing about science", he says, "is that it doesn't signify where you come from. It's what you do that matters".

Having graduated in chemistry at Leeds and completed a doctorate there on the thermodynamics of solutions, he took the advice of Fred Dainton, now head of the University Grants Committee (UGC), and went to Canada in 1952 to learn about spectroscopy. He wanted an academic job when he returned two years later, but the pickings were thin. Geoffrey Gee, who had just left the Rubber Producers' Research Association to take up a chair in chemistry at Manchester, offered him a job "provided you work in my field and bring the techniques you've learned to bear on my problems". Allen stayed for twenty years.

Gee taught him three things: that it was possible to do good physical science on polymers; that good science is always the basis of good technology ("That coloured the whole of my career . . . I never had the hang-up some of my contemporaries had that there was something nasty about industry"); and that "scientists have to think more widely than just being a scientist"—a view reinforced by contact in Manchester with Brian Flowers and Sam Edwards, his SRC predecessors.

Allen acquired his experience of administration and industry during the 1960s, sitting on government and SRC committees and consulting for companies. Then, in 1969, in a development he sees as a crossroads, Allen helped set up the ICI/Manchester Unit Joint Laboratory he directed at Manchester. He insisted from the start that the laboratory be closed after five years, on the grounds that any worthwhile work could at least be run down steadily, any dynamic work would be picked up by ICI or the university, and any decision to re-start it could take account of experience. A little later he went half-time to the ICI corporate laboratory, also for five years.

Before Allen came to the SRC he declared all his consultancies, but served notice that he might wish to take up two while in office; this was agreed. "It would be nice to do some consulting as a working scientist", he says, "and I could do this without compromising my position". For the curious, he says his income is likely

Professor Geoffrey Allen

to stay roughly the same at the SRC, with a "chance there could be a drop".

As for the coming four years, he knows the problems awaiting him. Support for high energy physics and space, for example, can't go any lower. "They're at the margin", he says. After a declining curve in the overall budget, he now wants a flat one; an inclining one, he acknowledges, would be too much to expect. But it will probably have to come out of a larger Science Budget, that is, economic growth. Among the arguments at his disposal for a greater share of that budget, however, is one that must appeal to the scientists who dispose of it: that applications for money clearly deserving support are being turned down.

Allen here distinguishes a lack of money from a surfeit of ideas. But both are problems, even if the former is sad and the latter a sign of health. He also says that the 'dual support' system for university research is not working, save in specific cases—as when the UGC had some money for new projects and could be persuaded to put it into the Interactive Computing project for British universities.

Allen also knows the standards he needs to follow. He says he'll be running "an open office", like Flowers and Edwards before him. He is conscious of a need for proper and responsible dealings with pressure groups, though he doesn't name names. He likes tackling problems, "provided they're amenable to logic", and, he says, "I can be persuaded to change my mind. Administrators must be able to do that".

He hopes to leave his successor with an operation looking as good as the one Edwards has left him. And like Edwards, he hopes to return to science, his first love. He still works at it, after all. Last year he got a grant from the SRC.

BRITAIN

ICRF appointment

The Imperial Cancer Research Fund has announced a new director for its research laboratories. Chris Sherwell reports

THE Imperial Cancer Research Fund (ICRF) last week announced the appointment of Walter Bodmer, Professor of Genetics at Oxford, to succeed the present director of its research laboratories, Dr Michael Stoker. Stoker, a virologist, leaves the post he has held since 1968 a year early, in September 1979, when he is 61; he returns to academic life and research in Cambridge. Bodmer, 41, a population geneticist involved more recently in immunology and tissue typing, has held his Oxford chair since 1970.

Bodmer said this week that nothing significant should be read into the fact that a geneticist was replacing a virologist. In welcoming the appointment, however, Stoker described the appointment of a geneticist as "very timely", paralleling in its recognition of contemporary developments his own appointment as a virologist years earlier. Over the next couple of decades, he said, the cancer problem would be dissected at the molecular genetics level, specifically in the realm of mutagenesis. Bodmer was "one of the leading younger geneticists in the country", with an all-round ability as well as a specialisation in the human leucocyte antigen (HLA) system.

Though Bodmer will almost certainly be receiving a higher salary than he currently enjoys, the real attractions are the opportunities, facilities and support ICRF offers. He recognises that he will be giving up one sort of administration for another, but hopes not to be too tied down by such matters. There will be no teaching, no university committees, a curtailed administrative load outside but—most importantly—an allotment of space at the ICRF's sophisticated laboratories in Lincoln's Inn Fields, central London. This he can fill with his own appointments—perhaps up to a dozen—who will continue the research he has led at Oxford, though perhaps with a change of emphasis. He says he will establish an HLA typing lab there.

In spite of recent allegations about the way ICRF uses its money, which drew a sharp response from ICRF and subsequently a libel suit for the paper that made them, Bodmer sees the job as no more controversial than any similar one in universities and other

research institutes which have to justify their particular paths in research. That the job is important he has no doubt—"otherwise I wouldn't be moving". It combines, he says, "the best opportunities for biochemical research in the country". But if the post hadn't come along, he would not be leaving the country, though he admits the alternatives beyond Oxford are limited.

Both Bodmer and Stoker believe in the virtues of limited tenure as a means of maintaining high quality in research. The same purpose is also served, both men believe, by the presence of foreign visitors, another distinguishing feature of ICRF research. Stoker is a firm advocate of another controversial view relating to research—that of early retirement from positions of power. This belief, along with his appointment as Foreign Secretary at the Royal Society, which has dragged him from his research, has encouraged his own departure. He adds that two years is the sort of notice that has to be given for a job like this.

Thus the far-reaching changes of which the ICRF Council chairman, Sir Eric Scowen, spoke in his annual report (published at the end of March) are now coming to pass. The announcement of a new man to head the biggest single private research effort in the country is the outcome of a search conducted by a special ICRF committee over the past few months. Stoker's intention to relinquish his post was confirmed in the annual report; and Stoker's deputy, Dr Renato Dulbecco, retired last month. The post of deputy will remain vacant until Bodmer takes up his appointment and makes his own choice. In the meantime the deputy's role is handled by Dr John Cairns, who heads ICRF's lab at Mill Hill. □

Walter Bodmer

USSR

Space retrieval

THE cancellation of the *Soyuz 25/Salyut 6* link-up coincided most unfortunately with the celebration meeting held on October 11 to mark the 20th anniversary of *Sputnik 1*. This anniversary had been invested with considerable importance by the Soviet authorities.

In his anniversary address, Academician Boris N. Petrov, head of the *Interkosmos* programme, did his best to retrieve the situation. Reviewing the events of the last twenty years, he stressed especially the successes of the automatic space probes and the *lunokhody* and Venus descent craft in particular. Even the *Salyut* space stations, he noted, were designed to operate in both manned and unmanned modes, and in either could "solve important problems of science and technology". Since the (manned) *Soyuz* programme already had two major setbacks in the past three years (*Soyuz 15* in 1974 and *Soyuz 23* in 1976 both failing to achieve a link-up with the *Salyut* stations), Petrov naturally concentrated on the more successful unmanned ventures.

Ironically, however, it was not the crew but the automatic part of the *Soyuz 25* mission which was responsible for its failure. The main part of the link-up programme is effected automatically by the *Soyuz* on-board computer with possibly some orbital adjustments of the *Salyut* by ground control. This system operates to within 120 m of link-up, after which the cosmonauts take over the control for final approach. What appears to have happened in recent aborted missions is that the automatic system has over-shot such that the *Soyuz* has not had sufficient power reserves to attempt a second, manually-controlled pass.

Although some *Soyuz* craft have carried solar panels to recharge their batteries, it seems likely that on the *Soyuz 25* these were sacrificed to permit additional weight to be allotted to stores and/or experimental equipment. This would tie in with speculations that the crew were to attempt to break the current Soviet record of 63 days or the US record of 84 days in space.

It is not impossible, however, that a further attempt to link up with *Salyut 7* will be made before the 60th anniversary of the Revolution next month.

Vera Rich

IN BRIEF

Call for dementia research

IN its report *Senile and presenile dementias: a report of the MRC sub-committee*, the Medical Research Council recommends that senile dementia and the rare presenile dementias be designated areas of high research priority, although it does not recommend setting up a special MRC Unit yet. The main message of the report is clear however; an estimated 5–10% of elderly people in the UK suffer from senile dementia about which virtually nothing is known. The MRC should encourage clinical units prepared to undertake the intensive studies needed and support special workers within institutions caring for demented patients, who would organise research and liaise with laboratory workers

carrying out parallel biochemical, pharmacological and histological studies.

One of the most urgent needs is a clarification of the various types of dementia and their comparison with the normal ageing process. Little is known about the early stages of senile dementia and the report suggests that community studies of the elderly might be grafted onto surveys already in progress for other purposes.

German nuclear funds

IN the Federal German government's budget proposals for 1978, DM1.45 thousand million is ear-marked for nuclear research and technology. Allowing for a 4% inflation rate, this means an increase of 8.5% over the

1977 figure of DM1.3 thousand million. As before, financing the government nuclear research centres will be a main consideration and DM700 million is being made available for their maintenance.

The prototype 300MW fast breeder reactor under construction at Kalkar is costing DM2.86 thousand million at present rates and 90% is being borne by the state, with the Belgian and Dutch governments contributing DM719 million. The cost of this reactor has greatly increased year by year—DM200 million from 1977 to 1978 alone—and its completion is expected in 1983. The costs of the 300MW high temperature reactor being built at Schmehausen are running at DM1.75 thousand million.

AGRICULTURAL technology in the USA has evolved with a rapidity that is seldom perceived except by participants in its use. The consequences of migration from rural to urban areas are evident to most people, but few city-dwellers know much about what happens on the farm these days.

The change from muscle-power to petroleum has proceeded almost to completion, and is to all intent irreversible. The Council for Agricultural Science and Technology recently published an energy-use report prepared by 22 agricultural scientists. They point out that to produce today's US crops by 1918 technology would require 61 million horses and mules that would need almost half of the cropland now in cultivation to supply their food. Performing the necessary additional hand labour thus involved would call for the relocation of almost one-third of the total working population in the United States. The average cost of their toil, at \$26.50 per day, would be about nine hundred times as much as the cost of electrical energy to carry out the same amount of physical work. Very few people have first-hand memories of how crops were raised and harvested 50 years ago, and not many can comprehend what life would be like if horses were, once again, the main source of transportation.

Agricultural production uses only 3% of the energy consumed in the USA. Jet aircraft use more than this. More food is being produced than ever before, and with less human labour. In 1976, the US gained \$23 billion in foreign exchange from exporting agricultural products, as compared with \$34 billion spent on imports of energy for all purposes.

One-third of the energy used in agriculture is employed for producing fertilisers, and only 5% for production of pesticides, principally herbicides, insecticides and fungicides. One estimate is that 41% of food and

Energy for crops**THOMAS H. JUKES**

fibre production in 1960 would have been lost if pesticides had not been used. Biological control as a replacement for chemicals is 'in the news', but, as the energy-use report says, "Biological control of plant pests is the ideal in theory, but progress in practical implementation is slow and difficult."

On 27 September the Secretary of Agriculture criticised the use of pesticides as being wasteful of petroleum. He did not mention that their production and application consume less than 0.2% of the country's energy total. I wonder how he allocates

priorities: certainly he doesn't seem to be 'thinking agriculture'. There is much dissipation of fossil fuel for purposes of convenience and pleasure as contrasted with its use for food production. Tourism and family reunions must account for a substantial proportion of jet plane travel. The highways are clogged with passenger automobiles and recreational vehicles, and the waterways resound to the hum of motorboats. Give us the petroleum-powered luxuries of life, and we will dispense with the necessities. Maybe! If food really becomes scarce, there will be plenty of trouble.

Statistics are dry and boring compared with the actual rural scene. Huge tractors till the vast wheat country, clean of officious fence or hedge, in the Great Plains. The big fields of hybrid maize in the corn belt grow apace in the hot sun, nourished by synthetic ammonia, and protected by chemical weed-killers. Further west, green discs of the new centre-pivot irrigation systems dot the landscape. These are yet another replacement of manpower by energy. There has been recent criticism of the University of California for developing new farm machinery that does the work of human beings. This is like protesting against the tractor, the combine, the plough and other inventions that lifted the burden of hand labour.

Only 5% of the energy used on farms is derived from electricity. Optimistically speaking, solar energy could perhaps supply another 25% by the year 2,000, says the report. When it comes to agricultural production, no complete or near-complete replacement seems to be in sight for the dwindling supplies of petroleum.

correspondence

Melatonin in serum

SIR,—We have recently completed a preliminary collaborative study of radioimmunoassay methods in the determination of melatonin in serum in which the different techniques used in seven laboratories were compared. To each laboratory we sent the same material derived from calf serum with a melatonin level of less than 10 ng per l. To this serum melatonin was added in a final concentration of 200 ng per l or 0.86 nmol per l. Three ml aliquots of the calf serum from the pool were pipetted into glass ampoules. The calf serum in each ampoule was lyophilised and the ampoules were tightly sealed. The serum was dissolved in 3.00 ml of water and melatonin was assayed in 35 samples from 8 ampoules and was found to be 0.87 nmol per l \pm 12.9% r.s.d. by our own radioimmunoassay.

Twenty ampoules were sent in December 1976 to each laboratory. They were requested to add 3.00 ml of water to each ampoule and to perform assays using their own method, reporting back the results in ng melatonin per l redissolved calf serum. The results of the different assays are given in Table 1, and are presented as ng per l and are also transformed to nmol per l according to the SI-system. It should be pointed out that the extraction techniques in the methods differed considerably between the different laboratories and that each laboratory used its own antiserum except for numbers 4 and 5 who used the same one.

The results indicate that melatonin can be measured accurately using different radioimmunoassay techniques. We now intend to repeat and extend the study to include human reference serum with different concentrations of melatonin. This will allow an evaluation of the linearity and parallelism of the standard curves, as well as give

further data on the sensitivity and specificity of the different assays. All laboratories wishing to participate in the extensive cross-validation study planned at the beginning of 1978 are welcome to submit their names to us.

Technics rather than technik

SIR,—I thoroughly agree with what Fores and Rey wrote (1 September, page 2) about the need for making a clear distinction between science and what they propose to call *Technik*. However, I should like to point out that a well-established, but now little used, word already exists in the English language for the concept of the useful arts. This is *technics*, and I would urge the revival of this old English word, rather than the importation of a foreign-sounding one, to describe this area of our culture.

Lewis Mumford's use of it throughout his great book *Technics and Civilization* (1934, Routledge) bears out what Fores and Rey say about the need for a word to express this concept; for Mumford, unlike Bronowski and Mazlish, does not make the mistake of confusing science and technics. As he says, "science and technics form two independent yet related worlds: sometimes converging, sometimes drawing apart".

As Fores and Rey indicate, this distinction is as important in current discussions and controversies concerning the place of science and technics in contemporary culture and society as it is in historical studies. Much current discussion of the financing, control and effects of 'science' would be far less

woolly-minded if a clearer distinction were made between science and technics. However, the lack of a familiar word to express the idea of technics is I think only part of the problem. Equally important is the (perhaps only partly conscious) desire by many scientists and others deliberately to blur the distinction, and to claim for 'science' and scientists the credit for all the benefits resulting from technics.

This shortsighted attitude may have boosted funding and respect for science in the short run but in the longer run, as people become more critical of technology, it is in part responsible for the increasing disillusion with science and the growth of antisience movements. The anti-science critics are even more at fault for failing not only to make a distinction between science and technics, but also between these and the socio-political decisions which have led to particular technical developments that they dislike, and for which we are all responsible as citizens, whether scientists, technicians (surely a better word than *Techniker*, if its status can be raised) or layman. For a healthy society and a healthy science I believe we should support those, like Sir Andrew Huxley (29 September, page 366), who insist on making these important, but often unpopular, distinctions.

The Messinian crisis

SIR,—Just a thought or two on "The Messinian salinity crisis . . . etc" by Adams, Benson, Kidd, Ryan and Wright (29 September, page 383).

A Crisis—a word often seen in the news. Is a term which most journalists

frequently use
With reference to sterling or else to a ban
On the import of Datsuns from far off Japan.

But vaporisation of Miocene seas
Is a natural process and nothing like these;
Evaporite bodies will oft mark the coast
Of an ancestral ocean which gave up the ghost.

Applying that hackneyed and trite little word
To a normal event is quite clearly absurd.
Else what might we see if left up to the Press—

The Messinian Horror or Shocker or Mess?

ANON

Comparison of different radioimmunoassays for melatonin

Laboratory Number	Melatonin concentration of reference calf serum containing 200 ng per l or 0.86 n mol per l.	
	pg per ml	nmol per l

Observation of photon antibunching

from Peter Knight

VERY few measurable optical effects require field quantisation and the idea of a photon for their explanation. One notable example of this rare class is photon antibunching in intensity correlation of resonance fluorescence (*Nature* **265**, 683; 1977), predicted by Carmichael and Walls (*J. Phys.* **B9**, L43; 1976; *J. Phys.* **B9**, 1199; 1976) and now observed by Kimble, Dagenais and Mandel (*Phys. Rev. Lett.* **39**, 691; 1977). Whereas most optical coherence and correlation experiments have an adequate semiclassical interpretation, antibunching requires quantisation of the emitted fluorescence and the idea of a 'quantum jump'.

The radiation emitted from the resonantly-excited atoms is collected, split into two, and imaged onto two photomultiplier tubes whose output is electronically correlated. The intensity correlation of interest is

$$g^{(2)}(\tau) = \frac{\langle \hat{I}(t+\tau) \hat{I}(t) \rangle}{\langle \hat{I}(t+\tau) \rangle \langle \hat{I}(t) \rangle}$$

where $g^{(2)}(0) = 2$ if the radiation was chaotic (this positive correlation, or bunching is the famous Hanbury Brown Twiss result) and $g^{(2)}(0) = 1$ for coherent light. Fully quantised and semiclassical approaches are here in agreement. However there are quantum states of the electromagnetic field which do not have a classical description, but the experimental realisation of such states has proved difficult. States exhibiting negative photoelectric correlation ($g^{(2)}(0) - 1 < 0$) or 'antibunching' are much-discussed examples of an effect requiring field quantisation: it is hard to visualise a function $I(t)$ representing the classical intensity whose mean square is less than the square of its mean. Carmichael and Walls showed that the resonance fluorescence radiated by a single two-level system driven by a coherent field possesses the required statistical properties to exhibit antibunching. This can be demonstrated easily since $g^{(2)}$ may be expressed in terms

of the two-level Pauli operators representing the atomic source fields as

$$g^{(2)}(\tau) \sim \langle \sigma_+(t) \sigma_+(t+\tau) \sigma_-(t+\tau) \sigma_-(t) \rangle$$

so that $g^{(2)}(0) \sim 0$. This behaviour at $\tau \sim 0$ is a strictly quantum feature: the atom emits a photon at time t and is unable to radiate again immediately after having made a quantum jump down to the lower state.

The measurement of $g^{(2)}$ consists of two parts: detection of the first photon (ensuring the de-excitation of the source atom) and a delay while the atom is re-excited by the resonant driving field for the subsequent re-emission of a second photon. So

$$g^{(2)}(\tau) \propto p(t, \tau)$$

where $p(t, \tau)$ is the probability of finding an atom, initially in its lower state at t , re-excited at τ . Cohen-Tannoudji (*Frontiers in laser spectroscopy*; Les Houches 27; North Holland, 1977) has stressed that the antibunching effect in resonance fluorescence is a striking example of wavepacket reduction in action. We expect first a lack of coincidence counts at short times τ , and further expect the Rabi nutational oscillation of $p(t, \tau)$ to be reflected in $g^{(2)}(\tau)$ which

should exhibit periodic bunching and antibunching as the driven atom undergoes Rabi oscillations. For a sufficiently intense resonant driving field for which the Rabi frequency Ω is much greater than the spontaneous decay rate β ,

$$g^{(2)}(\tau) = 1 - \exp(-3\beta \tau/2) \cos \Omega \tau$$

If there is more than one atom in the observation region the interpretation is a little harder and since fluorescence could then be produced by two or more atoms this would increase $g^{(2)}$ and obscure the antibunching.

The experimental arrangement of Mandel and coworkers resembles that used by earlier groups to study resonance fluorescence spectra. Sodium atoms in a well-collimated atomic beam are prepared by optical pumping to ensure a two-level transition and are driven by an intensity and frequency-stabilised CW dye laser at the $3^2S_{1/2} F=2, M_F=2$ to $3^2P_{3/2} F=3, M_F=3$ transition frequency. The fluorescence emitted at right angles to both atomic and laser beams is collected, divided by a beam splitter, imaged on to two photomultiplier tubes, and the correlation evaluated under computer control. The atomic beam current is designed to allow only one or two atoms to contribute to the collected fluorescence at the same time. The experiment shows direct evidence for antibunching of photoelectric pulses. After various corrections have been made for accidental pair correlations produced by background laser scatter, their results are shown in Fig. 1, where the broken curve shows the theoretical single atom prediction normalised to the same peak for $\Omega/\beta = 4$.

The observed $g^{(2)}(0)$ is approximately 0.4 rather than the zero predicted theoretically for a single atom. Mandel *et al.* estimate $g^{(2)}(0)$ to be 0.5 if the field were produced by two radiating atoms located at random positions. At large τ the atomic flight time through the photomultiplier field of view decreases $g^{(2)}(\tau)$. The overall result is as expected and plainly exhibits both bunching, and more importantly, for the first time antibunching. \square

Fig. 1 Values of $g^{(2)}(\tau)$ derived from the data, demonstrating photon antibunching. The broken curve is the theoretical prediction, suitably normalised to the same peak.

Immunoglobulin genes and the immune response

by Miranda Robertson

The Tenth Harden Conference on the Molecular Genetics of the Immune Response was organised by Professor A. R. Williamson and took place at Wye College on 12–16 September, 1977.

IN a meeting which was characterised throughout by lively and uninhibited discussion of almost every controversial issue in modern immunology, the outstanding topic was without question the unexpected character of immunoglobulin light chain chromosomal DNA. The surprise lies at the junction between the constant and the variable region sequences. S. Tonegawa and his associates have shown (Hozumi & Tonegawa *Proc. natn. Acad. Sci. U.S.A.* **73**, 3628; 1976) that whereas in embryonic cells the chromosomal DNA coding for the V region is on a different restriction fragment from that coding for the C region, in antibody-secreting myeloma cells they are both on the same restriction fragment. This has been widely interpreted to mean that V and C sequences are separated in the germ line, but become joined in committed B cells. But evidence from four sources, including Tonegawa's own laboratory, now shows that the V and the C sequences of myeloma chromosomal immunoglobulin DNA are separated by an untranslated 'spacer' sequence.

Discontinuous Ig gene

This explains the otherwise puzzling results of S-I nuclease digestion of hybrids between chromosomal DNA and cDNA made on a mRNA template. S. Longacre, as reported by B. Mach (Geneva University), hybridised separate V and C region cDNAs with restriction fragments of embryonic and myeloma chromosomal DNA, expecting to find more single-stranded tails on the embryonic than the myeloma DNA. But when she compared the hybrids retrieved by hydroxyapatite extraction with those retrieved from S-I nuclease digestion, which removes single-stranded stretches, she found that the proportions were the same for embryonic and myeloma DNA.

In a different experiment on similar principles, T. Rabbitts (MRC Cambridge) has compared the susceptibility of liver chromosomal DNA and myeloma chromosomal DNA hybridised with complete kappa chain cDNA to digestion with S-I nuclease. Liver

DNA is assumed to be equivalent to embryonic DNA where immunoglobulin genes are concerned, so that if separate V and C sequences are joined in plasma cells the entire V-C sequence should be protected by the cDNA probe in myeloma DNA, but only separate V and C fragments in liver DNA. In fact, gel electrophoresis of the digests reveals only the C region fragments regardless of the source of the chromosomal DNA. The fate of the V region is unknown—it may have undergone partial digestion or be hidden in the C region peak—but at the very least the data imply a gap between the V and the C regions in which a short stretch of single-stranded DNA is exposed to the nuclease. Similar nuclease digestion evidence for the separation of V and C regions of active immunoglobulin genes was presented by G. Mathysens (Basel Institute for Immunology), who, however, found both V and C region fragments on electrophoresis.

The results of the nuclease digestion studies are moreover fully borne out by electron micrograph evidence from Tonegawa's own laboratory, presented at the conference by O. Bernard (Basel Institute for Immunology). Hybrids of cloned myeloma chromosomal DNA with the complementary lambda chain mRNA showed clearly in the electron microscope a single-stranded stretch of DNA which appeared as a loop between the V and C regions. Approaching the question another way, Tonegawa and his colleagues have annealed separate V and C region mRNAs with double-stranded chromosomal DNA. Because the DNA hybridises preferentially with the mRNA, this results in openings in the double strand where the RNA has hybridised with one strand of the DNA. In the case of lambda chain mRNA, two such loops (known as R loops) are separated by a roughly 1,000-nucleotide 'spacer' sequence.

It seems likely that the 'spacer' DNA has some regulatory function and that function is not peculiar to immunoglobulin genes. There are strong indications, hammered home by Mach, that spacer sequences may be a general feature of eukaryotic genes. There have recently been reports in three other systems of discontinuous genes on chromosomal DNA—in adenovirus (see *News and Views* **268**, 101; 1977), in *Drosophila* tyrosinase tRNA (Goodman *et al. Proc. natn. Acad. Sci. U.S.A.*, in the press) and mouse globin (Leder *et al. CSH Symposium*, 1977). Although the spacer sequences are not

present in mRNA, that is not necessarily to say that they are not transcribed, and the obvious speculation is that the transcript is none other than so-called heterogeneous nuclear RNA. Many have remained unconvinced that hnRNA is anything more than an artefactual aggregate of mRNA molecules, but the evidence has recently become more convincing, at least for globin (see *News and Views* **269**, 9; 1977), and indeed according to Mach, Leder finds that the size of the globin spacer corresponds to the size of the extra sequence on globin precursor mRNA. Some first steps in investigating immunoglobulin precursor mRNA were reported at the conference by R. Wall (University of California, Los Angeles) who has identified 40S and 24S precursors of kappa light chain mRNA. He has yet to find out where the V and C regions map on these precursors and whether they will hybridise with chromosomal DNA.

The answers might have been available sooner had not the early stages of the work been held up by indecision on the part of NIH about the safety of the plasmids used by Wall to clone cDNA probes for the precursor mRNAs. Delays of the same sort are affecting Rabbitts and his colleagues who are waiting for permission to clone myeloma chromosomal DNA in an *E. coli*-λ phage EKII system. Now that it is clear that cDNA is by no means necessarily a copy of chromosomal DNA and that spacer sequences may hold the answers to important questions of genetic regulation, delays of this kind are likely to lead to acute frustration, particularly where, as in the case of Rabbitts's experiments, permission has already been granted elsewhere (in Switzerland and the USA). It may not matter very much in the light of eternity whether fundamental discoveries in biology are made now or in six months' time, in Britain or in the USA—but it matters very much to biologists.

Sequence diversity in frameworks

There are no sequence data yet on the myeloma gene, but Bernard did present the first nucleotide sequence of an immunoglobulin gene: that of a cloned V region fragment of embryonic chromosomal DNA, the fruit of a collaboration between Tonegawa's group and W. Gilbert's group at Harvard. This has revealed another untranslated region, 54 nucleotides long, in the precursor sequence at the 3' end. Otherwise, the sequence corresponds largely to the amino acid sequence of

the light chain V region of myeloma MOPC 315 which produces lambda chains of subgroup ii. A curious feature of the sequence is that at three of four of the positions where it disagrees with the MOPC 315 sequence it corresponds to that of MOPC 104R, which produces lambda i light chains; in the fourth position it agrees with neither. C. Milstein (MRC Cambridge) gave voice to a general feeling that this pattern of substitutions is unlikely to be random. More sequence data should clarify the issue, but in the meantime the data are reminiscent of the amino acid sequences of mouse kappa V regions, reported by M. Weigert (Institute for Cancer Research, Philadelphia). Some residues in these chains seem to switch between closely related subgroups.

Whether more amino acid sequence data will help to clarify the question of the generation of antibody diversity is controversial. Amino acid sequences were presented at the meeting in support of an insertion theory (D. Capra, University of Texas) and of a somatic mutation theory (Weigert) but neither set of data could strictly eliminate alternative theories. It is now generally conceded that antibody diversity arises by a somatic mechanism acting on a limited number of germ-line genes (probably two or three copies for lambda chains and perhaps two or three copies for each of an unknown number of kappa chain subgroups) (Rabbitts & Milstein *Contemporary Topics in Molecular Immunology* 6, 117; 1977; Tonegawa *et al. Immun. Rev.* 36, 29; 1977) and there is a school of thought that the solution to the generation of diversity will be found in cellular mechanisms rather than sequences. In the meantime, the rational position on GOD seems to be agnostic.

Idiotypes and immunoregulation

Sequence data may, on the other hand, help to clarify the structural and functional significance of idiotypes, which if Jerne is right may be the basis for intercellular recognition in a regulatory network. At what levels might Jerneian immunoregulation take place? Capra presented unequivocal evidence that the so-called 'anti-Ars' idiotypic on mouse anti-arsonate antibodies is determined by specific residues in the hypervariable regions which also determine antigen-binding specificity. However, there is ample serological evidence that idiotypic is not always associated with the antigen-binding site, and T. Feizi for instance (MRC Clinical Research Centre, Harrow) has found that cross-reacting idiotypes on human antibodies against erythrocyte Ii antigens can also be found on antibodies which lack that binding specificity. In competitive bind-

Unification confrontation

MOST physicists hope that the electromagnetic and weak interactions are unified and this hope has been strengthened over the past few years as the Weinberg-Salam unified model of the weak interactions has notched up success upon success. But a small cloud appeared on the horizon last year; and it has not gone away.

Take the Weinberg-Salam model, add some atomic physics calculations, and the result is a prediction of small, but measurable, parity-violating effects in atoms. Preliminary results from experiments aimed at detecting these effects were reported last year (*Nature* 264, 528; *News and Views* 264, 505; 1976) and were disturbing—the predicted effects were not seen.

These experimenters now have their final results (*Phys. Rev. Lett.* 39, 795; 39, 798; 1977) and have reached a sensitivity an order of magnitude better than the prediction. No parity-violating effects are seen and the threat to the unified theories must now be regarded as serious.

There is only one foreseeable escape route—perhaps the atomic physics calculations for the bismuth atoms used in these experiments could be in error. Experiments planned with hydrogen will resolve this final uncertainty.

ing assays, the idiotypes can be identified as a heavy chain framework determinant that seems to identify a sub-subgroup.

Subgroups of subgroups were a particular feature of Weigert's partial sequence data on 22 mouse kappa light chains, and raised the question of how variable a framework residue has to be before it becomes part of a hypervariable region. (Is GOD leaky? asked Milstein). Indeed Weigert and his colleagues have now found in mouse light chains a fourth distinct hypervariable region, like that reported earlier by Capra *et al.* in heavy chains. The fourth hypervariable region (like the second, at least in those antibodies whose crystal structure is known) is remote from the antigen-binding site.

F. Melchers (Basel Institute for Immunology) was enormously interested in these results, on the grounds that the fourth hypervariable region might provide the basis for recognition in Jerne's immune network. He has indirect evidence for idiotypic regulation of mouse antibodies to streptococcus A

carbohydrate, which carry the A5A idiotypic. Primary immunisation with either the streptococcal antigen or antibodies against the A5A idiotypic stimulates the production of idiotypic-positive antibodies 40% of which bind the antigen and 60% of which do not, regardless of the priming stimulus. Melchers interprets these results—which strictly apply only to lipopolysaccharide (LPS)-sensitive cells (one third of B cells) since LPS was used to expand the number of cells *in vitro* for counting—as evidence for lymphocyte triggering by idiotypic rather than by antigen-binding site in these cells.

The structural significance of idiotypic arose again in connection with the T cell receptor—another crucial element in any immune network. The recent discovery that T and B cells can carry the same heavy chain idiotypic and that anti-idiotypic antibodies can trigger T cell help *in vitro* (see *Cold Spring Harbor Symp. quant. Biol.* 61, 1976 and *News and Views* 263, 10; 1976) has been interpreted to imply a T cell antigen receptor coded partly by genes in the pool coding for the V region of the heavy chain. However, K. Rajewsky's group, as reported by T. Cramer and T. Imanishi (Cologne University), now finds that in SJL mice T cells but not B cells carry an idiotypic associated with the heteroclitic binding of the hapten nitrophenol (NP). Genetic experiments suggest that this heavy chain idiotypic is expressed only in cells which produce lambda light chains and its absence in SJL B cells is due to the very low production of lambda chains by that strain. This leaves a puzzle: what produces the conformational change that gives the idiotypic on SJL T cells? So far, the evidence has been against any light chain gene contribution to the 'T cell receptor.'

The proper characterisation of the T cell receptor will really be possible only when one can be isolated in large quantities. This may be soon. G. Fathman and H. Hengartner (Basel Institute of Immunology) reported a technique for producing 3-month cultures of T cells with specific reactivity in a mixed lymphocyte culture—a potential source of receptors for histocompatibility antigens.

'Hybridomas'

The final session of the meeting amounted to a progress report on the developing range of hybridomas. Since its beginning with immortal clones producing antibodies against sheep red blood cells, the hybridoma army has recruited clones producing antibodies against haptens TNP, NIP and NP; soluble proteins peroxidase, lysozyme, and chick gamma-globulin; and influenza virus surface antigens, rat

MHC antigens, T, G (A - - L) and streptococcus A carbohydrate.

To this Milstein added a line producing antibodies against an allotypic determinant on mouse molecules with the characteristics of IgD (Pearson *et al. Eur. J. Immun.*, in the press). and mouse hybrids producing antibodies against three rat bone marrow differentiation antigens (Williams *et al. Cell*, in the press). With some overlap, these antibodies seem to define the lymphoid, myeloid and erythroid populations of the bone marrow.

G. Hämmerling (Cologne University) reported the production of three hybrids secreting monoclonal antibodies against mouse H-2 antigens; these three are the survivors of five isolated from 1,000 hybridisations.

The recent extension of hybridisation techniques to T cells produced two exciting reports. Hengartner and Fathman have evidence for sensitivity to specific MHC haplotypes in two hybrids made from lymphoma cells and T cells sensitised to H-2 haplotypes in mixed lymphocyte reactions. And L. Herzenberg (Stanford

University), and colleagues has a hybrid expressing antigens coded by genes in the I-J region which is associated with T suppressor functions. The hybrid is derived from T cells in a mouse suppressed for the Ig1b allotype but evidence for a suppressor factor is so far inconclusive. Supernatants from the cultured cells have shown no reliable suppressor activity against the allotype, and although sonicates have given more positive results they too are inconsistent.

Research reported at the conference represented the entire immunological continuum between what Fathman characterised as immunochemistry on the one hand and immunomagic on the other. But although structures and sequences may be cleaner than cells and sonicates, there remain problems that at this stage are not amenable to the immunochemical approach. Herzenberg was prepared to defend immunomagic. Knowing the structure of the immunoglobulin molecule, he pointed out to participants who included R. R. Porter, has not told us how B cells work. □

arranged around the inner surface of the neck near the entrance hole or ostiole. Fertile female fig wasps, *Blastophaga psenes*, enter these winter figs and lay their eggs in the neuter flowers. On completion of their development, the male offspring emerge first and bore into the flowers occupied by females and fertilise them before emergence. The males then die. Females subsequently emerge from their pupae and leave the fig through the ostiole, but in doing so become coated by pollen from the dehiscent anthers of the male flowers.

Pollen-bearing female wasps are then believed to enter figs containing a mixture of female and neuter flowers. The former have longer styles than the latter, and this prevents oviposition by the fertile females. They do succeed, however, in ovipositing within the neuter flowers, where the next generation of wasps develop, and they also inadvertently scatter their load of pollen within the fig, resulting in the pollination and subsequent fertilisation of the female flowers.

Emergence and fertilisation of the wasps takes place as before, and the fertile females now escape and invade a third type of fig which contains only neuter flowers. At this stage, obviously, there is no pollination process, but a third generation of wasps can be established within the neuter figs. Fertile females of this generation emerge in winter and lay their eggs in the neuter flowers of the winter fig (which also contains male flowers) thus completing the annual cycle.

Of most immediate interest is the provision by the plant of certain flowers, and indeed an entire inflorescence generation, which are of no

tors. There are on record some striking examples of complex symbiotic relationships between plants and pollinators, but few more remarkable than that of the figs (*Ficus* spp.) and the fig wasps.

The false fruits of the figs are hollow, swollen receptacles which bear on their inner surface small, unisexual flowers. In the wild progenitor of the edible fig (*Ficus carica*) a specialised winter fig is formed which contains mainly neuter flowers, with some male flowers

Figs for wasps

from Peter D. Moore

THE phenomenal success of the flowering plants may well be due, at least in part, to the way in which their floral evolutionary development has been related to the structural and behavioural modifications of insect pollina-

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

A hundred years ago

THE NORWEGIAN DEEP-SEA EXPEDITION The next day was wonderfully calm, but the fog covered the higher parts of Jan Mayen. We went on shore the sea being so calm that we could step on short without any inconvenience. The shore consisted of volcanic ash and sand, quite black, and was, higher up, covered by driftwood thickly strewn on a level surface. To the left

was a steep cliff wonderfully rich in colour, the abode of thousands of seabirds, whose inner slope, consisting of ash and scoriae, showed it to be a part of a former crater. The scientific party spread in different directions and made the best of the time in surveying, collecting specimens of plants and rocks, and drawing; one polar fox was killed. The plants found belong to very

few species, the vivid green we had seen from the ship being only a cover of moss. The flowers had just come out and all the lower part of the island up to about 2500 feet was generally free from snow, the snow lying only in the lower regions where a larger mass was gathered in ravines.

From *Nature* 16, 18 October, 526; 1877.

direct value in terms of seed production. The energy expenditure must be worthwhile in terms of maintaining a pollination vector population for the time when they are needed.

The wasps themselves have also attracted some attention recently, for the process of pollen transfer has proved more complex than was originally anticipated. It is difficult to account for pollination by a simple accidental carriage of pollen by emergent females, for as the wasp enters the ostiole of the receptor inflorescence, it is subjected to considerable mechanical stress as it forces its way between tight ostiolar scales. Indeed the entry slits are so narrow that wings and antennal flagellae are often lost. Thus the likelihood of pollen being carried into the fig inflorescence by superficial adhesion is very low. Galil and Eisikovitch (*Tijdschr. Ent.* **112**, 1; 1969) discovered specialised pollen pouches on the ventral side of the thorax in the fig wasp *Ceratosolen arabicus*, which is the pollinator of the African *Ficus sycamorus*. In the same year Ramirez (*Science* **163**, 580; 1969) described similar pouches in New World species of fig wasps. Subsequently Galil and Snitzer-Pasternak (*New Phytol.* **69**, 775; 1970) described the behaviour of the fig wasp *Blastophaga quadraticeps* as it loads and unloads pollen from its pollen pockets during pollen transfer in *Ficus religiosa*. Cleaning movements of the legs transfer pollen to the thorax and the pouches open at the touch of the legs to receive pollen. So, in many fig wasps complex morphological and behavioural adaptations aid the process of pollen transfer, which in turn ensures the fertilisation of fig ovules.

But this does not seem to work in the case of *Blastophaga psenes* and the common fig *Ficus carica*. Galil and Neeman (*New Phytol.* **79**, 163; 1977) have re-examined this relationship and have found no evidence of the complex pouches which had been noted in other fig wasps. Yet the superficial carriage of pollen was most unlikely, for not only does the wasp experience physical scouring when passing between ostiolar scales, it also cleans itself very thoroughly after emergence from the *Ficus* inflorescence and removes all external pollen.

Serial sections of wasps were taken immediately after this cleaning and the only pollen to be found was that lodged in temporary folds within the intersegmental membranes. Galil and Neeman also found that these invaginations are produced as a result of water loss from the insect after emergence from the pupa which causes infolding of the membranes. About 20–30% shrinkage of the abdomen was found to occur within the fig inflores-

cence after emergence from the pupa. They experimentally raised the relative humidity of some figs to 100% and found that wasps failed to pick up pollen.

Unloading in the receptor fig probably occurs in the reverse manner. On entering a higher humidity atmosphere the wasp's body would swell and the pollen trapped in folds would be liberated. Thus the transfer of pollen in *Ficus carica* is more complex than originally thought, but it entails neither the sophisticated anatomical modification nor the purposive behavioural mechanisms on the part of the vectors which are found in other fig/fig wasp relationships. Galil and Neeman point out that the common fig has about 800 stamens in a fig, compared with only about 15 in *Ficus religiosa*, the vector of which has pollen pockets. The relationship in *Ficus carica* can thus be regarded as evolutionarily primitive and energetically expensive and wasteful as far as the plant is concerned, for most of the pollen produced and disseminated is cleaned off by the unwitting vector. □

Origin of the Rio Grande rise

from Peter J. Smith

THE Rio Grande rise is a large, well known, aseismic structure stretching through at least 10° of both latitude and longitude to the west of the mid-Atlantic ridge in the South Atlantic Ocean. To say that it is well known, however, is to imply little more than that it is a conspicuous topographic feature which has received a certain amount of bathymetric attention and frequent mention in the geophysical literature. It is true that Thiede is about to publish a report (*Am. Assoc. Petr. Geol. Bull.*) in which he concludes from sedimentary and stratigraphic data that the rise was once a large island which lay 2–3 km above sea level some 75–85 Myr ago. But the origin of this sediment-covered and supposedly sunken island remains uncertain, largely because of lack of information on the nature of the basement.

Unfortunately the recent attempts by the Deep Sea Drilling Project to sample the igneous basement beneath the Rio Grande rise were unsuccessful (Leg 39, site 357). On the other hand, as Fodor *et al.* point out (*Earth planet. Sci. Lett.* **35**, 225; 1977), a large quantity of igneous material was dredged from the rise by the research

vessel *R. D. Conrad* in 1973. Dredge samples are obviously not as satisfactory as cores recovered from *in situ* rock; nor in the present case have the samples been dated. Nevertheless, from microscope, electron microprobe and bulk chemical studies on a selection of the 1973 dredge material, Fodor and his colleagues have been able to come to some general conclusions about the origin of the Rio Grande rise.

The material in question comprises basaltic rocks, some of which contain mafic nodules and megacrysts, and volcanic breccias composed largely of basaltic fragments. The bulk compositions enable the rocks to be classified as alkalic basalts, trachybasalts and trachyandesites. Moreover, the compositions of the pyroxene, plagioclase and interstitial alkali feldspar within the material are typical of volcanic rocks having alkalic affinities. The dredged samples are thus clearly characteristic of alkali basalt suites and bear no resemblance to oceanic ridge tholeiites. The compositional range (basalt to trachyandesite) also shows that the volcanic material of the Rio Grande rise has undergone magmatic differentiation.

Both alkalic composition and differentiation seem to be typical features of aseismic ridges. Indeed, the Rio Grande samples are very similar in many respects to those from the islands of Gough and Tristan de Cunha and, more significantly, to those from the Walvis ridge, the linear structure whose position almost mirrors that of the Rio Grande rise across the mid-Atlantic ridge. On the other hand, there are some distinct differences between the Rio Grande and Walvis rocks, which fact draws attention to the disadvantages of having to use dredge samples. It is reasonable to assume (although it cannot be proved) that the material dredged from the Rio Grande rise comes from the crystalline basement. But how typical is it of the basement? Does it or does it not represent all the main rock types present? There is no way of knowing. Thus the observed differences between the Walvis and Rio Grande rocks may (but also may not) simply reflect inadequate sampling. Moreover, the impossibility of knowing whether or not the sampling is representative makes it impossible to say that the Rio Grande basement does not also include tholeiitic material.

But these reservations apart, the best information available suggests that the Rio Grande rise consists of alkalic basaltic rocks covered with later sediment. And as alkalic basaltic rocks in oceanic provinces are usually associated with volcanic islands or seamounts, it

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

seems reasonable to propose, as do Fodor and his colleagues, that the rise originated as a series of volcanic islands and/or seamounts which underwent magmatic differentiation and subsided as the South Atlantic opened. The evidence for subsidence is that the Rio Grande sediment contains shallow-water fossils incompatible with its present depth. Those same sediments also contain little or no volcanic material, suggesting that the igneous activity represented by the dredge samples must have occurred early in the South Atlantic's history.

However, the question of how the volcanic islands formed is still unsolved. They appear to be consistent with generation at a hotspot, although volcanic activity along fracture zones cannot be ruled out. The origin of the Walvis ridge is similarly uncertain.

European tree-trunks reveal post-glacial changes

from J. M. Fletcher

A symposium on Dendrochronology was held on 19 August, 1977, as part of the X INQUA Congress at Birmingham.

DENDROCHRONOLOGY, the dating of wood remains by the number and pattern of tree-rings has been extensively used to date wooden artefacts and timber structures from prehistoric to relatively modern times (see *News and Views* 268, 402; 1977). Some of the research reported at the symposium demonstrated that the type of tree-ring analysis involved is also revealing and dating major changes in palaeogeography over the past 10,000 years and calibrating radiocarbon ages with greater accuracy than hitherto.

In Europe, Bruno Huber (1899–1969) established German preeminence in this subject and this position is being maintained by the work of his pupils, in particular by that of B. Becker (University of Hohenheim, Stuttgart). From his comprehensive study of the subfossil tree trunks that lie at various depths in the sediments occupying former river channels in central Europe Becker has been able to trace and date with precision changes in fluvial activity and in climate from 9,600 BP (in

Preboreal time) to 780 AD, after which few trunks were deposited in the drainage systems studied.

The information on climatic changes has been derived from the changes in species present in the immediate post-glacial period and from the dating by dendrochronology of 2,000 oak tree-trunks in association with the variations in their average ring-widths (that is growth rates) at different times in the Holocene.

Periods at which depositions ceased simultaneously occurred in several river systems, for example the Danube, Rhine, Main and Werra. At other periods, for example 6,700 to 4,500 BC, the ring-widths and associated remains from peat indicate a slow rate of growth due to wet sites with a high ground water level.

The dates of major changes in the drainage system are pin-pointed by these results. For example, in late Atlantic times there was renewal of trunk accumulation due to high fluvial activity from 4,300 to 3,100 BC. Becker interprets his results for the Late Holocene as providing evidence not only for the activity of the rivers, but, from changes in the widths of the annual rings, for the clearance of forests by man with the production of deep alluvial soils.

A paper of particular interest to those concerned with the calibration of radiocarbon dates dealt with results at Queen's University, Belfast on large samples (175–200 g), each covering 20 years growth, of the sub-fossil oaks already dated in the same department by tree-ring analysis. After a lengthy period of critical examination of the human and other errors that can arise in radiocarbon analysis, G. Pearson has achieved an accuracy in which the uncertainty on each of many results is as little as ± 25 yr. The importance of this accuracy, which is comparable to that (about ± 20 yr), now achieved at Seattle by M. Stuiver on comparable samples of recent wood, lies in the reliability of the information for the first period to be examined systematically, namely from 3,600 to 4,600 BP. Whereas previous results from US laboratories a decade or so ago were interpreted as showing distinct 'wiggles' in that part of the calibration curve, the Belfast results virtually conclusively demonstrate their absence.

Two papers in the session dealt with conifers at the timberline in the Alps. Françoise Serre (Laboratory for Palaeobotany and Palynology, Marseilles) has discovered what may well be some of Europe's longest-lived trees. Most of the 38 larches sampled at an altitude of 2,100 m in the Maritime Alps (France) are over 1,000 years old. About 20% of their ring-width sequen-

ces have been cross dated and the 'signature' years compared with climatic variations. The research extends to about 500 km, the distance in the Alps over which ring-width features for this species are common to particular years.

For the eastern Alps, the High Tavern of Austria, H. W. Posamentier (Department of Geosciences, Rider College, New Jersey) described how narrow and wide rings of stone pine and larch at the timberline are related to records of glacier advance or retreat. For stone-pine, the correlation coefficient (r) is -0.69 for the years 1891–1969. The tree-ring record implies 10 or 11 periods of glacier advance since 1585: these include the years 1627–28 and 1815–22 when ring-widths were at their lowest values. □

Snow geese, lizards and sunbirds

from John Krebs

The 15th International Ethological Conference was held at Bielefeld, FRG on 25–31 August, 1977.

THERE are two genetically distinct colour phases of the lesser snow goose, *Anser caerulescens* breeding in Northern Canada. At the Eastern end of Hudson's Bay the large La Pérouse Bay colony contains 25–30% 'blue' and 70–75% 'white' morphs. At the conference, F. Cooke (Queens University, Ontario) described a remarkable long term study of the mating preferences of the two colour morphs. At La Pérouse Bay, most birds choose a mate of their own colour: only 16% of all pairs are mixed, compared with an expected 40% if birds had been choosing mates at random. In a series of experiments with captive geese, Cooke was able to show that the bird's preference for a mate of its own colour comes about through imprinting (learning during early life). The field observations and experiments established the following facts. Birds of mixed parentage choose mates at random with respect to colour, so that own colour has no direct effect on mate choice. In order for a clear preference to be established, a young bird has to grow up with parents and siblings of the same colour. Birds reared with parents and siblings of different colours showed no clear mating colour preferences, although they did avoid mating within

J. M. Fletcher holds a Leverhulme Trust Fellowship granted through the University of Oxford to the Research Laboratory for Archaeology and History of Art.

John Krebs is Lecturer in Zoology at the Edward Grey Institute of Field Ornithology at the University of Oxford.

their own foster group (an interesting parallel with learned 'incest' avoidance in human children). How do mixed pairs arise in nature? Cooke constructed a model based on the observed facts, and was able to show that about 40% of the offspring from pure broods must be mating at random in order to account for the observed level of mixed pairs. An appreciable proportion of birds become imprinted on the 'wrong' colour as a result of nest parasitism, for example a blue pair laying an egg in the nest of a white pair, but this alone is not enough to account for the high level of 'mistakes'. Cooke suggests two possible additional hypotheses: there is genetic variation in imprintability, or birds take a mate of the wrong colour when there is no alternative around. Cooke's study is the clearest demonstration of sexual imprinting in the wild, but the selective forces acting on the snow goose polymorphism are still a mystery. White, blue, and mixed pairs all have similar reproductive success, yet the frequency of morphs varies from one colony to another. Whether this reflects an historical accident, or the action of unidentified selection pressures remains to be discovered.

The phenomenon of sexual imprinting itself is hard to explain in functional terms. Why should birds have to learn their mating preferences rather than having a purely inborn response to their own species? P. P. G. Bateson (University of Cambridge) proposed the intriguing idea that sexual imprinting is primarily involved with recognition of kin. Bateson argued that animals should avoid mating with their own siblings (because of the adverse effects of inbreeding), but they should also prefer to mate with partners from the same population, whose genes will be adapted to the same environmental conditions. The simplest way to achieve this optimal level of outbreeding would be to learn the phenotypic characteristics of close kin, and choose a mate which is similar but not too similar to the parents and siblings. This prediction could well be tested experimentally.

Although the main theme of the conference was behavioural ontogeny, there were several outstanding contributions dealing with more ecological problems. J. A. Stamps (University of California at Davis) described how young lizards (*Anolis aeneus*) defend feeding territories, and in addition that the level of aggression shown to tethered conspecific intruders depends on the size ratio of resident to intruder. The lizards are most aggressive to individuals of the same size, which have the biggest overlap in feeding niche, and are hence the most severe competitors. L. L. Wolf (University of

Syracuse, New York) and F. B. Gill (University of Pennsylvania, Philadelphia) also reported on a study of feeding territories, and described how sunbirds (Nectariniidae) utilise their defended feeding area in a way which results in an individual avoiding recently depleted flowers so that they always harvest from those flowers which have been accumulating nectar for a long time.

Finally, T. H. Clutton-Brock (University of Cambridge) showed in a most elegant study how red deer stags settle disputes over the ownership of females by roaring contests, in which there is a gradual escalation of roaring rate until the loser gives up, presumably exhausted. There remains the nagging question of why a weak stag does not lurk in the background while two stronger males roar each other to exhaustion, and then step in to claim the hinds. □

Origin of cosmic rays

from a Correspondent

The 15th Biennial International Cosmic Ray Conference was held at Plovdiv, Bulgaria on 13-26 August, 1977.

SOMEWHERE in the Universe cosmic ray nuclei are produced and accelerated up to energies as high as 10^{20} eV. The bulk of cosmic ray nuclei, falling at the rate of $10^4 \text{ m}^{-2} \text{ min}^{-1}$ on the Earth's atmosphere, are known to be single protons and to have energies $\sim 10^{10}$ eV. The flux of such particles falls off steeply with energy ($\approx E^{-2}$) so that at 10^{20} eV the rate is very low indeed, 1 per 10 km^2 per 10 years. The propagation paths of the cosmic ray particles are stirred up by interstellar magnetic fields to such an extent that nearly all sense of source direction is lost. Thus the origin of cosmic ray particles remains a continuing topic for debate, and pervaded the conference. No definite solution was to emerge but some progress was achieved.

Experimentally the main attacks on the problem are concerned with the determination of the mass composition, the energy spectrum and the arrival directions of the cosmic ray particles. At lower energies ($\sim 10^{10}$ eV) interest still focuses on the relatively recent discovery of ultraheavy cosmic ray nuclei. New results were presented by the combined University of Bristol/

Dublin Institute for Advanced Studies group on the analysis of large balloon-borne lexan plastic and nuclear emulsion sandwich stacks flown from Sioux Falls, USA. A total exposure of 120 m^2 days was achieved at $\sim 3.8 \text{ g cm}^{-2}$ atmospheric depth. A total of 274 tracks of nuclei with charge number $Z > 36$ were found, of which 96 had $Z > 65$. The charge distribution featured a peak in the neighbourhood of platinum and a high uranium group flux. The conclusion appears to be that these particles are produced by rapid neutron capture (r-process) presumably in supernovae or similar outbursts.

At higher energies up to 10^{17} eV and beyond the evidence with regard to the overall mass composition is very indirectly obtained and with controversy existing as to interpretation it is probably best (but not necessarily safe) to conclude that the mass composition is much the same as that found at lower energies, that is, 90% protons, 9% helium nuclei, 1% rest, at a fixed energy per nucleon.

For many years now it has been well established that the energy spectrum steepens significantly beyond 10^{15} eV although the explanation of the steepening remains in doubt. New results presented at the conference from the large Extensive Air Shower Arrays at Haverah Park (England), Yakutsk, (USSR), and Volcano Ranch (USA) consistently indicate a flattening in the spectrum again at close to 10^{19} eV. This flattening may perhaps represent a transition from dominantly galactic rays to extragalactic sources.

Any weight given to this latter conclusion must be strongly influenced by the almost complete isotropy in arrival directions of cosmic ray particles up to the highest energies. Harmonic analysis in right ascension of the data at these highest energies ($> 10^{18}$ eV) does suggest a measurable anisotropy creeping in, but the phase seems to change with energy and no obvious source direction is indicated. Some of the highest energy events clearly come from high galactic latitudes, strongly suggesting extragalactic origin.

The outstanding problem for protagonists of the extragalactic origin rests with the lack of cut-off above 10^{19} eV expected from the interaction of the high energy particles with the universal 2.7 K photons. This suggests that the particles observed at these energies come from distances within 10^8 light years.

In the opening invited talk at this conference V. I. Ginzburg (Institute for Nuclear Research, Moscow) argued forcefully that as the galactic halo had now been well established from radio astronomy, there really was

no problem in the bulk of the cosmic rays being of galactic origin. Later in a more detailed analysis of the situation V. S. Berezinsky (Moscow) maintained the Soviet line by suggesting a theory that could fit the total experimental data. According to his 'naïve theory', at energies below 10^{19} eV cosmic rays are mostly protons of galactic origin. The phase of anisotropy varies with energy due to a focusing effect of the galactic magnetic fields. At higher energies an origin transition occurs with the cosmic rays reaching the Solar System largely coming from the local supercluster of galaxies with a maximum from the Virgo direction. For the moment this theory of the origin of cosmic ray particles seems to be the best compromise. □

Do populations regulate themselves?

by Mary Lindley

A symposium on Population Control by Social Behaviour was held at the Institute of Biology in London on 20–21 September, 1977. It was organised by D. M. Stoddart (King's College, London) and F. J. Ebling (University of Sheffield), and the proceedings will be published by the Institute of Biology.

TWENTY years ago V. C. Wynne-Edwards propounded a hypothesis to explain why populations of animals do not expand unchecked until stopped by the exhaustion of food resources. Many and perhaps most animals, he suggested, must regulate their population densities before this stage is reached, and they do that through social competition. His work on the red grouse (*Lagopus lagopus scoticus*), which was carried out at the University of Aberdeen and which he recalled at the symposium, proved him correct as far as that species was concerned. Each autumn young males take up territories in a contest with established males, and the many unsuccessful birds are cast out and usually die within six months. Thus population density is regulated.

One of the purposes of the symposium was to examine how much more evidence has emerged in favour of the hypothesis. Some of the eleven speakers addressed that theme more directly than others.

Reviewing 30 years of field work

with great tits (*Parus major*) in Oxford and Holland, J. R. Krebs (University of Oxford) said that the birds' behaviour seems to affect population size during three stages of the annual cycle. First, during the spring breeding season the number of eggs laid by each bird can fluctuate considerably, with fewer produced when the population density is high than when it is low. This fluctuation does not seem to be a direct consequence of changes in the amount of food available. The immediate influence is more likely to be a behavioural mechanism. Second, the survival of young birds in the summer and early autumn is an important influence on the size of the population, and aggressive interactions are at least in part the cause, with heavier birds most likely to survive. The third period when behaviour seems to be regulating population is early spring, when birds compete for territories, and exclude those that are unsuccessful. But Krebs stressed that little is known about the environmental resources to which the regulating behaviour is geared.

Indications of similar regulatory influences on populations of the woodmouse (*Apodemus sylvaticus*) have emerged from equally long term studies carried out in the United Kingdom and elsewhere in Europe. J. R. Flowerdew (University of Cambridge) described how from winter to winter the number of woodmice within a population remains relatively stable. From summer to summer, however, there is considerable variation and the population is smaller in summer than in winter. The size of the winter population seems to be regulated by a density-dependent process initiated in summer. Social behaviour seems to be a part of that process, involving, for example, aggression towards immigrants and dispersal of juveniles. But more information is needed about the nature of the behaviour and about the influence of other factors, especially genetics, predation and starvation.

In primatology, however, positive conclusions seem even further away. Although primates might seem to be ideal mammals for the study of social behaviour and population structure, most of them live too long. A. Jolly (University of Sussex) pointed out that there has been pathetically little long-term fieldwork with primates. Hope is offered, however, by the lemurs of Madagascar which have a relatively short life cycle. Since 1963 sixteen studies have been carried out in the favourable circumstances of the Barenty Reserve, and although the objectives have been different in each case, the data can be combined to

represent a long-term study of the sifaka (*Propithecus verreauxi*) and *Lemur catta*. A picture is emerging of stable populations, with *P. verreauxi* maintaining the same territories throughout the year and from year to year, while *L. catta* fluctuates in its use of the environment. This seems to be an ideal situation for critical study of social behaviour and population regulation. And that was as far as Jolly was prepared to go.

Her fellow primatologist J. Deag (University of Edinburgh) seemed to offer even less hope. He launched an attack on primatologists, including himself, for the way they have generally discussed the adaptive significance of social behaviour. He criticised the approach of inductive reasoning, whereby hypotheses are developed to explain behaviour on the assumption that it is adaptive. This had led to much speculation, with in many cases alternative hypotheses which are difficult or impossible to test. Deag called for a more critical approach based on established facts and involving more rigorous testing of the predictions of hypotheses.

There is growing evidence that odours are involved in many inter-relationships between behaviour and population processes in mammals. Reviewing what is known so far, D. M. Stoddart (King's College, London), explained that data on the role of odours in reproduction are hard to interpret because all were obtained in the laboratory, which is very different from the field. But three aspects of population ecology provide a function for odour. First, social dominance can be marked by odour in several species, including rabbits and marmosets. The emerging picture is of a rise in social dominance associated with increased production of scent, increased marking behaviour and a change in the composition of the odorous secretions. Second, odour can be used to mark out and maintain territory. It chiefly deters intruders and serves as a landmark by which the occupier recognises its own territory. Third, odour seems to be involved in the transmission of danger and warning signals, although so far the evidence is not strong. As Stoddart pointed out, the role of odour in population regulation is another underdeveloped area of investigation.

By the end of the symposium the only conclusion to have emerged was the familiar plea that more work needs to be done. Wynne-Edwards professed himself completely content that discussion about his hypothesis is still alive. As he said, you cannot expect answers of the sort given at meetings of the British Association in Victorian times. □

review article

Recent excitement in the DNA replication problem

Bruce Alberts* & Rolf Sternglanz†

It is now possible to reproduce most of the reactions involved in DNA replication using prokaryotic enzymes in vitro. Such systems have revealed that DNA replication is a complex process depending on a relatively large number of proteins, and that nucleoside triphosphate hydrolysis energy is used at several discrete steps. Much of the complexity of DNA replication may arise from the need for extreme copying fidelity.

DNA REPLICATION represents a central biological problem whose general outlines were solved "in theory" by Watson and Crick. For the past 24 years, geneticists, biochemists and molecular biologists have been hard at work attempting to translate into chemical reality the prediction that "each chain acts as a template for the formation on to itself of a new companion chain"¹. Progress has been slower than many had expected, as both the mechanism and the enzymology have turned out to be surprisingly elaborate. The following general conclusions concerning events at a functioning replication fork now seem reasonable, and will be used as section headings in this brief review of the present status of the field. Note that we have not attempted to deal with the important problem of how replication forks are initiated, but only with how, once formed, they progress along the parental helix to duplicate the DNA.

DNA is replicated by a multienzyme complex

DNA is replicated by means of a multienzyme complex, sometimes called a "replication apparatus". This complex, because it is held together by relatively weak protein-protein interactions, has been isolated only as smaller individual protein components. Much of the challenge in this field is a consequence of the difficulty of recognising these components in cell extracts, and then purifying them and characterising their activities in larger reconstituted systems.

The first components to be identified were of course the DNA polymerases, the intricate and elegant enzymes which catalyse the actual polymerisation process, while following the dictates of the base sequence of a DNA template strand². These large enzymes (molecular weight about 10^5) have so far failed to receive the attention they deserve from enzymologists, chemists and X-ray crystallographers. As a result, we know rather less

about their detailed chemistry than we should, despite some intriguing initial studies³.

Because it is smaller and simpler than the DNA polymerase, considerable attention has been paid in recent years to defining the chemistry and structure of a second component of the replication apparatus, henceforth designated the "helix-destabilising protein" (abbreviated as HD-protein)[§]. The prototype for proteins in this class is the T4 HD-protein (T4 gene 32 protein), originally designated a "DNA-unwinding protein"⁵, and in more recent years called by some a "DNA-melting"⁶ or "DNA-binding"⁷ protein. Quantitative data reveal that by binding tightly, co-operatively and specifically to single strands, the T4 HD-protein and its analogues in other organisms greatly reduce the thermodynamic cost of DNA helix melting within the cell^{5,6,8,9}. However, as discussed below, additional energy seems to be needed to open the parental DNA helix ahead of the fork. Further, HD-proteins interact in specific ways with many other proteins which function on DNA, and can thereby play a deciding part in determining their mode of action^{7,10-13}.

The other proteins which interact with the DNA polymerase and helix-destabilising protein to complete a replication apparatus are less well characterised. Here geneticists have contributed much to recent advances. Their work forecast the complexity of *in vitro* systems now in use, revealing as early as 1963 a requirement for numerous gene products in a large replication apparatus^{14,15}. Moreover, the many mutants they isolated made it possible for biochemists to develop "*in vitro* complementation assays". Such assays, which quantify the activity of mutationally defined proteins, have allowed numerous essential proteins of previously unknown function to be identified and purified to near homogeneity from *E. coli*^{10,11}, bacteriophage T4^{16,17} and bacteriophage T7¹⁸⁻²⁰ replication systems. The development of an *E. coli in vitro* DNA replication system using only soluble components²¹ was another major advance. So far, the number of putative replication fork proteins identified by genetics and/or biochemistry is at least 13 from *E. coli*^{10,11}, 6 from the T4 system^{17,22} and 4 from the T7 system^{18-20,23}. Possibly some of the extra proteins in the *E. coli* system are essential because the assembly of the replication complex needs to be much more carefully controlled in a bacterium than in a bacteriophage.

An interesting and so far unexplained feature of these multienzyme complexes is the large number of different replication proteins which hydrolyse nucleoside triphosphates to nucleoside diphosphates and inorganic phosphate. These include *dna* B protein²⁴, copolymerase III*²⁵, replication

*Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143.

†Department of Biochemistry, State University of New York, Stony Brook, New York 11794.

§ The new term "helix-destabilising protein", and the HD-protein abbreviation, are suggested here after consultation with other workers in this field. They are designed to avoid confusion with other types of proteins which seem to use ATP hydrolysis energy to aid in DNA-helix unwinding (see text). As an example of the convention proposed, the extensively characterised *E. coli* (3) and calf (4) analogues of the T4 HD-protein (gene 32-protein) are to be designated henceforth as the *Eco* HD-protein I and the calf HD-protein I, respectively. This nomenclature is designed to be descriptive enough to emphasise the striking homologies which exist between HD-proteins from different organisms, without focusing on any one of the possible consequences of thermodynamic DNA double-helix destabilisation (e.g., double-helix unwinding, acceleration of DNA renaturation, and single-strand extension; see ref. 5).

Fig. 1 *a*, Schematic representation of a replication fork, in which synthesis on the leading and lagging strand differs, but is carried out by the same type of DNA polymerase. *b*, Lagging strand synthesis in more detail: a cycle of synthesis and degradation of the RNA primer believed to start Okazaki fragments (for details, see ref. 38).

factor Y²⁶, *rep* protein²⁷, and presumably DNA gyrase²⁸ from *E. coli*; gene 44/62 protein and gene 41 protein from T4^{22,29}; and gene 4 protein from T7³⁰.

Fidelity constraints on the mechanism probably generate the observed asymmetrical replication fork

Most of those working on the biochemistry of DNA replication in the early 1960s tended to view replication as a relatively simple process. Cairns had shown by autoradiography that the two parental polynucleotide chains become separated from each other, and at about the same time become paired with newly made complementary chains, at a structure termed a "replication fork"³¹. The simplest mechanism to draw was one in which DNA polymerases continuously elongate the DNA chains on the two sides of this fork. Because of the antiparallel orientation of strands in the DNA double helix, only one of these DNA polymerases could proceed by chain elongation in the 5' to 3' chain direction (by attack of a 3'-OH of a polymer chain end on the activated 5' end of an incoming 5'-deoxyribonucleoside triphosphate monomer). A second type of DNA polymerase had to be postulated for which the growing chain end carried the 5' triphosphate activation, and the incoming 5'-triphosphate monomer was "backed in" to present its 3'-OH for the polymerisation reaction. Efforts to find such a second DNA polymerase were unsuccessful. Moreover, pulse-labelling with ³H-thymidine revealed 1,000–2,000 nucleotide-long "Okazaki fragments" of DNA at the growing fork³², apparently synthesised in the 5' to 3' chain direction only³³, and subsequently joined together by DNA ligase^{34–36}. These observations suggested that at least one of the two daughter DNA chains grows discontinuously at the replication fork, and in conjunction with detailed electron microscopic analysis of replicating molecules³⁷, led most workers in the field to switch to favour the type of model for replication schematically illustrated in Fig. 1*a*. Here, because of the asymmetry of synthesis on the leading and lagging sides of the fork, only a DNA polymerase which elongates chains in the 5' to 3' direction is required. However, fresh complications arise from the (at first sight perverse) inability of known DNA polymerases to start DNA chains *de novo*^{2,39,40}. Such new chain starts are

required at frequent intervals on the lagging side of the fork (Fig. 1*a*). Partly for this reason, a new primer-generating polymerase was sought, and eventually found in the *E. coli* replication system⁴¹. Its properties, combined with data from another system^{42,43}, made it seem likely that Okazaki fragments are initiated on short RNA primers which are elongated by DNA polymerase and then erased (and replaced by DNA) before DNA ligase-catalysed sealing of the lagging-strand DNA fragments. One such hypothetical cycle of primer synthesis and degradation is schematically illustrated in Fig. 1*b*.

The type of mechanism outlined in Fig. 1 seems at first sight much more complex and unwieldy than necessary. Is it possible that nature has been foolish and wasteful in engineering these crucial processes? In attempting to answer this question, it is important to recognise that DNA replication must be extremely accurate. Indeed, the observed templating fidelity is such that only one mistake is made per 10⁹ to 10¹⁰ base pairs replicated in *E. coli*⁴⁴.

The initial finding that DNA polymerases require a pre-existing primer chain to begin synthesis^{39,40}, began to be understood in the context of fidelity when it was found that for polymerisation, both T4 and *E. coli* DNA polymerases demand a Watson-Crick base-paired residue at the 3'-OH terminus of the primer to which nucleotides are being added. When confronted with a template-primer with a terminal mismatch, these polymerases use their built-in 3'→5' exonuclease activity to clip off unpaired primer residues by hydrolysis; this continues until enough nucleotides are removed to regenerate a base-paired terminus and create an active template-primer⁴⁵. As a result, these polymerases will efficiently remove their own polymerisation errors^{46–49}. As demonstrated by studies with mutant DNA polymerases^{48,49}, this self-correcting feature allows the enzyme to select for the proper template base-pairing of each added nucleoside triphosphate in a separate backward reaction, in addition to its strong selection for base-pairing of nucleoside triphosphates during the initial polymerisation. Theoretically, the intrinsic mistake frequency at this first step due to base mispairings can be reduced by the same factor in the proofreading step. It has been argued from chemical considerations⁵⁰ that the intrinsic mistake frequency is unlikely to be less than 10⁻⁵. In this case, at least one proof-

reading step would be absolutely required to approach a tolerable mutational load ($10^{-5} \times 10^{-5} = 10^{-10}$).

Accepting this view, it becomes clear why no DNA polymerase is able to start a new polynucleotide chain *de novo*, whereas DNA-dependent RNA polymerases can do so. We postulate that the need to be self-correcting gives DNA polymerase a stringent requirement for a perfectly base-paired primer terminus; to ask this enzyme to start synthesis in the complete absence of primer, without losing any of its discrimination between base-paired and unpaired primer 3'-OH termini, seems contradictory. In contrast, the RNA polymerases need not be self-correcting, inasmuch as relatively high error rates can be tolerated during transcription.

This line of reasoning likewise suggests a possible explanation for the failure to find a second DNA polymerase which adds deoxyribonucleoside 5' triphosphates in such a way as to cause chains to grow in the 3'→5' direction, despite the relatively simple type of replication fork mechanism that this would allow. With such a 3'→5' polymerase the growing 5' chain end (rather than the incoming mononucleotide) carries the activated triphosphate. Thus, mistakes in polymerisation cannot be hydrolysed away without a special enzymatic system for reactivating the bare 5' chain end thus created.

Finally, this view suggests why an erasable ribonucleotide-containing primer might be preferred for priming, rather than a non-erased DNA primer which might otherwise seem more economical. The argument that a self-correcting polymerase cannot start chains *de novo* also implies its converse: that an enzyme which starts chains *de novo* cannot do a good job of self correcting. Thus, any enzyme which primes discontinuous synthesis will of necessity make a relatively inaccurate copy (say, more than one error in 10^5). Even if the amount of this copy which is retained in the final product constitutes only 1% of the total genome (say, 10 primer nucleotides per 1,000 nucleotide Okazaki fragment), the resulting increase in overall mutation rate could be substantial. Thus, it seems reasonable to suggest that the use of ribonucleotides in synthesis of primer was of great evolutionary advantage, since it automatically marked these sequences as "bad copy" to be removed.

In conclusion, it seems likely that the type of mechanism for DNA replication sketched in Fig. 1 was specially selected to ensure that the entire DNA sequence is very accurately copied (that is, copied by a self-correcting type of DNA polymerase). Additional complexities in the mechanism, including the poorly understood requirements for protein cofactors which hydrolyse nucleoside triphosphates to nucleoside diphosphates (see above), may be similarly designed to help generate fidelity in as yet unexplained ways (see, for example, refs 51 and 52).

ATP energy can be used to aid DNA helix-unwinding at the replication fork

The early suspicion that cellular energy sources might be directly used to aid in the mechanics of DNA helix-unwinding^{53,54} has been dramatically confirmed by recent data. The first direct hint that this might be the case was the discovery of *E. coli* "DNA-unwinding enzyme I"^{55,56}. This enzyme, whose function *in vivo* is still unknown, can denature DNA only when it hydrolyses ATP, like the ATP-dependent nucleases discovered earlier^{57,58}. Later, a different *E. coli* DNA unwinding enzyme was identified, and found to correspond to the *rep* gene product²⁷. Like the above ATP-dependent enzymes, the *rep* protein can be assayed as a DNA-dependent ATPase, with ADP and P_i as products. In a recent elegant series of experiments, the *rep* protein has been shown to be necessary for DNA polymerase action on a double-helical template. Specifically, ϕ X174 double-stranded DNA circles have been used for efficient synthesis of single strands of viral DNA by the combined action of: a four-protein complex called *E. coli* "DNA polymerase III holoenzyme", *rep* protein, *Eco* HD-protein, and the ϕ X-coded *cis* A protein^{27,59}. In this reaction, the *cis* A protein nicks the (+) strand of the circular ϕ X DNA at a unique site, and attaches covalently to the 5' end of the

Fig. 2 Possible energetic contributions to helix unwinding. HDP stands for helix-destabilising protein (see footnotes). For a description of HD-protein, unwinding enzyme and DNA gyrase, see text. The arrows show the expected directionality of the motion generated by unwinding enzyme and by DNA gyrase, respectively, due to conformational changes occurring when bound ATP is hydrolysed by these proteins^{27,28}. The assignment of unwinding enzyme to the lagging strand side of the fork is rather arbitrary, and is based upon the fact that stoichiometric quantities of *E. coli* DNA-unwinding enzyme I seem to invade a DNA double helix by "walking" along a single strand from its 5' toward its 3' end⁶³.

DNA. The adjacent 3'-OH end created serves as a primer for the DNA polymerase, which in conjunction with HD-protein and *rep* protein synthesises the (+) strand in a modified "rolling-circle"⁶⁰ mode of replication. Approximately two molecules of ATP are hydrolysed per deoxyribonucleotide polymerised in this system.

The hydrolysis of one ATP molecule releases about 14 kcal of free energy at intracellular concentrations of ATP, ADP and P_i ⁶¹. The energy cost of melting a base pair on the template should range from about 1.2 kcal mol⁻¹ ($\frac{A}{T}$ next to $\frac{A}{T}$) to 5.0 kcal mol⁻¹ ($\frac{C}{G}$ next to $\frac{C}{G}$), depending on the particular base pair being melted and its nearest neighbour. (These numbers were derived for RNA helices at 25°, but values for DNA helices should be similar⁶².) Thus, coupled ATP hydrolysis can in principle make a significant contribution to parental DNA helix unwinding.

How an unwinding enzyme such as the *rep* protein may function in the replication of double-stranded DNA is schematically illustrated in Fig. 2. This scheme is designed to take into account the following facts: (1) only catalytic amounts of the *rep* protein are required for DNA synthesis²⁷; (2) the *rep* protein can hydrolyse ATP and cause DNA strand separation with *Eco* HD-protein even in the absence of DNA polymerase^{27,59}, and (3) unidirectional mechanical motion can result from coupling the hydrolysis of a bound nucleotide to allosteric changes in protein conformation (as in muscle)^{64,66}. From a recent report, the T7 gene 4 protein seems to perform a function similar to that of *rep* in the T7 DNA replication system³⁰.

Nevertheless, additional data make it clear that ATP-driven unwinding enzymes are only one of several kinds of components contributing to helix unwinding. First of all, while T7 gene 4 mutants are conditional-lethal and fail to replicate T7 DNA, all known *E. coli* *rep* mutants are viable (the rate of *E. coli* replication fork movement is slowed by only half when the *rep* gene is mutated; ref. 66). Second, an exciting new *E. coli* enzyme, DNA gyrase, has been discovered which uses ATP energy to pump negative twists into the DNA double helix²⁸, as schematically illustrated in Fig. 2. Such negative super-twisting will make the DNA helix easier to open by an estimated 1 kcal mol⁻¹ base pairs (M. Gellert, personal communication; see also ref. 67). DNA gyrase is inhibited by the drugs novobiocin⁶⁸ and nalidixic acid (M. Gellert, personal communication; N. Cozzarelli, personal communication). Since these drugs stop DNA replication immediately in *E. coli* (and many other prokaryotic systems), the contribution of DNA gyrase to helix unwinding in these system may be essential.

Finally, an important contribution to helix unwinding is

likely to be made by the helix-destabilising proteins. Apparently homologous HD-proteins have so far been found in a wide variety of organisms, including T4 and T7 bacteriophages^{5,69} *E. coli*³, *Ustilago maydis*⁷⁰, and calf⁴. As described above, *Eco* HD-protein is required for the catalytic *rep* protein-mediated DNA melting observed with ϕ X174 DNA in the presence of the ϕ X *cis A* protein^{27,59}, although its energetic contribution to melting is not yet known. Similarly, while the T4 DNA polymerase cannot displace strands on double-helical templates by itself, the addition of intracellular concentrations of T4 HD-protein to the complete T4 *in vitro* replication system allows this enzyme to proceed through double-stranded DNA at close to the rate *in vivo* of 800 nucleotides per second¹⁷. ATP hydrolysis by the T4 44/62 protein is required for this synthesis, but the stoichiometry of coupled hydrolysis is apparently less than 1 ATP hydrolysed per 5 deoxyribonucleotides polymerised (J. Barry and B. M. Alberts, unpublished results).

Since no DNA gyrase seems to be used in the T4 *in vitro* system (E. Belikoff and R. Sternglanz, unpublished results), a great deal of the 12→50 kcal mol⁻¹ required to melt one helical turn (10 base pairs) of DNA in this system may have to come from T4 HD-protein binding to the single-strands produced, as schematically illustrated in Fig. 2. Recent studies carried out on the T4 HD-protein⁶ would suggest that inside the cell, not more than 10 to 20 kcal mol⁻¹ helical turn melted should accompany its binding (assuming a concentration *in vivo* of about 10⁻⁵ M). However, stronger binding is seen when the C-terminal 8,000-dalton segment of T4 HD-protein is removed proteolytically, and the interesting suggestion has been made that the known interaction of T4 HD-protein with DNA polymerase⁷¹ and other T4 replication proteins²² similarly increases this energy of DNA binding at the replication fork⁷².

To summarise the situation as it seems to be now, a large part of the energy required for DNA helix unwinding ahead of the DNA replication fork can, in principle, be derived from the sum of the several forces illustrated in Fig. 2. No one of these proteins need be sufficient to accomplish the task alone. Surprisingly, different replication systems seem to use a different balance of the mechanisms illustrated, in some cases all three. Finally, the fact that DNA polymerase I of *E. coli* can use double-helical DNA templates in the absence of any of the proteins in Fig. 2 (ref. 2) means that considerable energy for helix unwinding can also come from the deoxyribonucleoside triphosphate hydrolysis which accompanies polymerisation. We can assume that the replicative DNA polymerases also derive energetic contributions to helix unwinding from this source.

Okazaki fragments need not all arise from *de novo* priming events

In this section we discuss the current status of work on the nascent DNA chains known as Okazaki fragments. Referring to the replication fork shown in Fig. 1a, it is clear that the lagging strand must be synthesised discontinuously with *de novo* priming events. Electron microscopic evidence demonstrates that such priming events occur at least every few kilobases³⁷. In principle, the leading strand can be synthesised continuously, with no *de novo* priming events (except possibly at the origin of replication). However, early work on *E. coli* and T4³² showed that after a short pulse of ³H-thymidine, all the labelled DNA is found as slowly sedimenting chains in alkaline sucrose gradients (10S, corresponding to 1,000–2,000 nucleotides). Thus, the data suggested that both strands are synthesised discontinuously. Experiments with DNAl igase^{73,74} and DNA polymerase I mutants⁷⁵ reinforced this idea, since such mutants accumulate 10S fragments even after relatively long labelling periods, with little or no label found in large DNA. Demonstrations that *E. coli*⁷⁶ and phage P2⁷⁷ accumulate more fragments on the lagging strand than on the leading strand have been reconciled with the above observations by noting that the fragments on the leading strand are joined more rapidly than those on the lagging strand^{78,79}.

Fig. 3 A possible scheme for the excision-repair of uracil from DNA⁸². The phosphodiester backbone of the DNA is represented by ...P-dR-P-dR..., N represents any of the 4 normal bases (A, G, C, T) and U represents uracil. The repair process takes place on double-stranded DNA, but the complementary chain has been omitted for simplicity. *a*, Uracil *N*-glycosidase⁸³ removes uracil, leaving an intact phosphodiester backbone with a missing base. *b*, Apurinic endonuclease cleaves the DNA chain at the missing base⁸⁴. Recent data indicate that an alternative pathway, in which endonuclease V⁸⁵ recognises uracil and cleaves the DNA chain directly, is less active. *c*, DNA polymerase I and its associated 5'→3' exonuclease nick-translates⁸⁶, removing the damaged region and filling in the gap. Finally, DNA ligase joins the nick⁸⁴ to complete the process.

However, recent work reveals that not all DNA fragments labelled during a short pulse need arise from *de novo* priming events. In an *E. coli* mutant originally called *sof* (an acronym for small Okazaki fragments), pulse-labelling yields nascent DNA chains 5–10 times smaller than normal⁸⁰. It has now been demonstrated that *sof* mutants are identical in genotype and phenotype to *dut* mutants, deficient in dUTPase⁸¹. Such mutants have a higher than normal ratio of dUTP to TTP, and some dUTP is therefore incorporated into the DNA. The uracil is then rapidly excised by an excision-repair system which leaves temporary breaks in the DNA. Cells have a repair system to remove uracil residues from DNA, probably because of the frequent spontaneous deamination of cytosine in DNA to yield uracil, which is a potentially mutagenic event. A hypothetical scheme⁸² for the uracil excision-repair process is presented in Fig. 3.

In view of the above results with *dut* mutants, the question arises whether some Okazaki fragments in wild-type (*dut*⁺) strains are due to uracil incorporation and subsequent excision, rather than to true discontinuous synthesis. Even with a very active dUTPase there should be a finite level of dUTP available for polymerisation in the cell. In several *in vitro* DNA replication systems, low concentrations of dUTP strongly affect the size of the fragments synthesised (ref. 87; I. R. Lehman, personal communication). Conceivably then, all of the fragments on the leading strand (and some on the lagging strand) could be due to uracil misincorporation and subsequent excision-repair. If this were so, one might expect only 50% of a ³H-thymidine pulse-label to appear in Okazaki fragments in a uracil *N*-glycosidase mutant (see Fig. 3a). But pulse-labelling experiments have shown no difference between this mutant

(*ung*; ref. 88) and wild type (I. R. Lehman, personal communication; R. Sternglanz, unpublished results). Although results in the expected direction have been observed with the *ung* mutant in a cellophane disk *in vitro* system⁸⁷, the relevance of this result to the *in vivo* situation is unclear.

It should also be pointed out that other repair processes may similarly act on the nascent DNA to give rise to Okazaki fragments⁸⁹. For example, *E. coli* *dam* mutants (deficient in DNA adenine methylase) exhibit abnormally high recombination frequencies⁹⁰ (as do the *dut* mutants⁹⁰), presumably because of nicks and gaps in the DNA. Thus, the delayed methylation of nascent DNA could reduce its size. Because of such possibilities, the important question of what fraction of Okazaki fragments arise from *de novo* priming events remains unanswered, as does the question of whether the leading strand is synthesised continuously or discontinuously.

The priming mechanism for Okazaki fragments is complex

As discussed above, at least some of the Okazaki fragments on the lagging strand (and possibly on the leading strand) must be due to *de novo* priming events catalysed by an enzyme other than DNA polymerase. There are several important questions about such priming. Is the primer RNA and does it have a unique length and sequence? Are there unique start and stop signals for the primer on the template strand? Finally, what proteins are required for synthesis of the primer?

Definitive work on the priming of Okazaki fragments comes from a study of polyoma DNA fragments synthesised in an *in vitro* nuclear system. These fragments have been shown to have a 10-nucleotide-long stretch of RNA at their 5' ends, terminating in a 5'-triphosphate. The RNA is homogeneous in length but the sequence is not unique, not even at the RNA-DNA junction^{42,91}. Comparable results have been reported recently for human lymphocyte DNA fragments synthesised in an *in vitro* replication system⁹². However, it is still possible that an Okazaki fragment from a unique region (for example, isolated by hybridisation to a specific small polyoma DNA fragment) has a unique RNA primer sequence.

It has proved more difficult to demonstrate the presence of an RNA primer on *E. coli* Okazaki fragments. The most direct evidence comes from studies on fragments synthesised *in vitro* in toluenised cells; in that case a RNA-DNA junction has been chemically demonstrated⁹³. However, the evidence for RNA on *E. coli* DNA fragments synthesised *in vivo* is much more indirect. The initial experiments involving density shifts in Cs_2SO_4 equilibrium gradients⁹⁴ are now known to have been unreliable^{91,95}. The main evidence comes from experiments in which the nascent chains are treated with alkali, which hydrolyses the presumed RNA primer leaving a DNA chain with a 5'-OH terminus. The presence of the 5'-OH is then demonstrated by digestion of the DNA with spleen phosphodiesterase⁹⁶ or by phosphorylation of the DNA chain with polynucleotide kinase^{93,97}. However, it should be noted that the production of a 5'-OH terminus after alkali treatment of an Okazaki fragment does not prove the existence of RNA on the chain. For example, the presumed intermediate in the excision of uracil from DNA (Fig. 3b) might yield a 5'-OH terminus after alkali treatment, due to hydrolysis of the terminal deoxyribose from the chain via a 3'-4' cyclic phosphate intermediate^{98,99}. Direct demonstration of ribonucleotides on Okazaki fragments⁹⁷ is complicated by the difficulty in purifying the DNA free from traces of contaminating RNA chains. No one has been able to find on the 5' ends of *E. coli* Okazaki fragments the triphosphates that are found on fragments from mammalian cells^{91,92}.

As mentioned previously, *E. coli* DNA polymerase I mutants accumulate Okazaki fragments. They presumably do so because of a defect in a reaction termed nick-translation; in this reaction, DNA polymerase I can use its 5' to 3' exonuclease to remove the RNA primer from the 5' end of an Okazaki fragment, while simultaneously filling in the resulting gap with DNA⁸⁶. Those

mutants with the most severe defects in nick translation are actually conditional-lethal¹⁰⁰. Thus, one would predict that at least some of these mutants would accumulate the RNA primer. This prediction has been borne out in two laboratories using the aforementioned criterion of a 5'-OH terminus on the DNA chain after alkali treatment (ref. 97 and D. Denhardt, personal communication). However, two other laboratories have been unable to detect an RNA primer using the same or similar mutants (ref. 101; and B. Olivera, personal communication).

It is surprising that it has been so difficult to demonstrate directly the existence of RNA primers at the 5' end of Okazaki fragments synthesised *in vivo*. Some workers remain sceptical about the *in vivo* existence of RNA priming for this reason. On the other hand, it is not unreasonable to postulate that the primer is normally very rapidly removed *in vivo*, being preserved only in *in vitro* replication systems where the primer removal mechanism has been altered.

The enzymology of priming has been worked out in some detail for the *in vitro* replication of 3 different single-stranded circular bacteriophage DNA molecules; their conversion to the double-stranded form is carried out by the host *E. coli* replication proteins. Since these small DNA molecules do not have ends, DNA synthesis is absolutely dependent on the synthesis of a primer. Historically, RNA priming was first discovered in one of these systems¹⁰². Even though the priming reactions are carried out on specialised single-stranded DNA templates, they serve as possible models for the priming of Okazaki fragments at a replication fork.

The protein requirements for priming depend on the particular single-stranded bacteriophage DNA template used. For DNA from the filamentous bacteriophages, M13 and fd, the *E. coli* RNA polymerase responsible for most cellular RNA synthesis produces an RNA primer, initiating synthesis at a unique place on the single-stranded, circular DNA template^{102,103,104}. For bacteriophage G4 DNA, the primer is produced instead by the *E. coli* *dnaG* protein, an enzyme which, surprisingly, can polymerise either ribo- or deoxyribonucleoside triphosphates *in vitro* with nearly equal efficiency¹⁰⁵. This primer also begins at or near a unique site on the G4 DNA. It has recently been reported that the *dnaG* protein requires ADP in addition to the nucleoside triphosphates (ribo- or deoxy-) in order to form a primer on G4 DNA¹⁰⁶. For both M13 and G4 DNA, primer formation also requires enough *Eco* HD-protein I to completely cover the single-stranded DNA¹⁰³⁻¹⁰⁶.

Priming on bacteriophage ϕ X-174 DNA is much more complex. The *dnaG* protein synthesises the primer in this system as well, but at least 6 additional proteins are required: *Eco* HD-protein, *dnaB* and *dnaC* proteins, and additional DNA replication factors termed either X, Y and Z^{10,26} or i and n¹⁰⁷. These proteins, in an ATP-dependent reaction, are thought to form sites on ϕ X-174 DNA that can be recognised by the *dnaG* protein, which in turn synthesises the primer at these sites^{107,108}.

Since genetic evidence indicates that *dnaB*, *dnaC*, and *dnaG* proteins are all required for *E. coli* DNA replication, it seems likely that the mechanism of primer synthesis for *E. coli* Okazaki fragments is similar to that found for ϕ X-174 DNA. In fact, the *dnaG* protein has been indirectly implicated in the initiation of *E. coli* Okazaki fragments¹⁰⁹. Questions which remain to be answered for both ϕ X and *E. coli* primer formation include: (1) the exact role of the proteins whose action precedes the actual *dnaG* protein-mediated primer synthesis, and (2) the composition and sequence of the primer (RNA or mixed RNA-DNA copolymer).

The analogous RNA priming reactions detected in the bacteriophage T4 and T7 replication systems are as yet less well characterised; for discussions see refs 17, 20, 22, 29 and 30.

Prospects and conclusions

In spite of the reservations expressed above, the basic outlines

of DNA replication fork enzymology are now clear. DNA replication is a complex process, in which the asymmetric replication fork shown schematically in Fig. 1a moves along the parental DNA helix at rates of up to 1,000 nucleotides per second (in prokaryotes). In this process, multiple protein components, including DNA polymerases, helix-destabilising protein, DNA unwinding enzymes, DNA ligase, and RNA primer synthesising and erasing enzymes all have an important role. Several purified systems have been developed from prokaryotes which come close to reproducing this basic reaction *in vitro*.

DNA synthesis on the lagging side of the fork is clearly discontinuous, and the present evidence suggests that synthesis on the leading side of the fork may often be discontinuous too. One possibility is that lagging and leading strand syntheses are coupled, perhaps by a protein-induced folding of the DNA at the fork into an unique tertiary structure.

An unforeseen aspect of the replication process is the widespread use of ribonucleoside triphosphate hydrolysis energy. Presumably, each hydrolysis event drives an ordered allosteric change in protein conformation⁶⁴. Some of these changes generate force to aid in parental DNA helix unwinding^{27,28,56}, while others may exist only to facilitate protein-protein assembly reactions^{29,110} and/or to enhance replication fidelity^{51,52}.

In this connection, fidelity is a crucial aspect of the *in vivo* replication process which has not yet been adequately examined in any *in vitro* system. We have proposed above that the enormous replication fidelity which must be maintained *in vivo* (one error in 10⁹ to 10¹⁰ bases copied) has placed severe restraints on possible replication mechanisms. In fact, much of the apparent complexity of the process may arise for this reason. Yet, present *in vitro* systems are routinely assessed as "faithful" by criteria (infectivity or restriction mapping) which would probably detect errors only if they exceed one part in 10⁴. Thus, until a more sensitive assay for fidelity is used, these *in vitro* systems cannot be said to be truly "biological." They may even be missing central protein components which have little or no effect on synthesis rates, but which have major effects on fidelity.

In eukaryotes, replication forks must progress over bound nucleosomal histones, which may explain in part both the slower rate (100 nucleotides per s) and the smaller size of Okazaki fragments (a few hundred nucleotides) compared with prokaryotes¹¹¹. Replication over nucleosomes demands major conformational changes in the chromatin¹¹², which probably cannot be achieved *in vitro* without eukaryotic replication proteins. If only for this reason, the enzymology of a eukaryotic replication system needs to be worked out in detail, and a purified multi-component *in vitro* replication system developed, analogous to those discussed above from prokaryotes. Also to be learned from such a system is the source of the high fidelity in eukaryotic replication, especially if the eukaryotic DNA polymerases turn out to lack the 3' to 5' proofreading exonuclease of the prokaryotic enzymes^{111,113,114}.

We thank all those investigators who sent us preprints before publication. This work was supported by grant number GM 24020 from the National Institutes of Health, while R.S. was on sabbatical at the University of California.

'Unmixing' of the deep-sea record and the deglacial meltwater spike

W. H. Berger, R. F. Johnson & J. S. Killingley

Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093

The Berger-Heath model of vertical mixing in deep-sea sediments provides a simple means of simulating an original input signal by 'unmixing' a signal found in deep-sea cores. When applied to an oxygen isotope record from the western equatorial Pacific, the possibility emerges that the entire ocean was covered by a low salinity water layer, during deglaciation.

DELETERIOUS effects of burrowing organisms on the resolution of the deep-sea record have been recognised for some time, and several mathematical models have been proposed to deal with signal distortions introduced by benthic mixing¹⁻⁵. The simplest one of these models² postulates a homogeneous layer at the sediment-water interface within which incoming particles are completely mixed with older sediment. In reality, of course, the intensity of mixing decreases with depth. In fact, mixing processes show a tiered structure, with intense mixing in an upper layer which is virtually homogeneous, and 'lumpy' mixing in a layer below. Sporadic displacement of sediment by large deeply burrowing organisms occurs to considerable depth. The upper two tiers of the entire mixed layer are of the order of 5 cm thick each, in the deep-sea carbonates studied, and the deep burrowing involves a layer at least 40 cm thick^{6,7}.

In spite of this complicated structure of the mixed layer, simple mathematical models can yield excellent results in simulating actual mixing processes. In particular, it can be shown that the distribution of particles within many ash layers found in deep-sea cores can be reconciled with a history of sudden emplacement of a thin homogeneous layer and subsequent simple exponential mixing⁸⁻¹⁰.

It seems worthwhile, therefore, to try to run the mixing model backwards, in order to reconstruct a stratigraphic signal as it might have appeared had there been no benthic mixing to distort it. Here we derive a simple unmixing equation and apply it to an oxygen isotope record of deep-sea carbonates from the western equatorial Pacific, spanning the past 20,000 yr.

Unmixing equation

The pertinent differential equation is derived as follows: c_0 is the concentration before mixing of some stable tracer, within the accumulating sediment; the concentration in the mixed layer is c . For discrete particles with any kind of label (such as forams and

their isotopic composition) $c = nr$, where n is the particle concentration and r is the average tracer value.

When a thin layer of sediment, dl , accumulates, it brings with it $c_0 dl$ units of tracer per unit area. At the same time, the mixed layer moves up a distance dl and so loses cdl units of tracer. The concentration of the tracer in the mixed layer then changes by an amount,

$$dc = (c_0 dl - cd)/m$$

dividing by dl , we get $c' = (c_0 - c)/m$; which means that the instantaneous gradient incorporated into the historical layer reflects the difference in the incoming signal (at the top of m) and the outgoing one (at its bottom), averaged over m .

Hence, to recover the original concentration c_0 from the record, we write

$$c_0 = c + c'm \quad (1)$$

This is the basic unmixing equation. In this model, the signal begins at the base of the mixed layer. When calculating sedimentation rates from a dated c_0 excursion, this shift has to be taken into account, that is, the distance to the sediment surface has to be reduced by m , before dividing by the age.

If sizeable changes occur in the proportion of signal-carrying particles, that is, in the proportion of the foraminifera whose isotopic composition is being studied, equation (1) has to be expanded. In the coarse sand fractions non-carbonate can be neglected, hence n , the particle concentration, is $s \times p$, where s is the grain size fraction and p the proportion of the species within that fraction.

The unmixing equation is applied first to n (that is, $[s \times p]$)

$$n_0 = n + n'm$$

and subsequently to $n \times r$

$$n_0 \times r_0 = n \times r + [n \times r]' \times m$$

and the solution sought is

$$\begin{aligned} r_0 &= n_0 \times r_0 / n_0 \\ &= (n \times r + [n \times r]' \times m) / (n + n'm) \end{aligned}$$

Table 1 Locations of box cores, depths from which they were raised, average carbonate content, and depth of the preservation spike at 14,000 yr b.p.¹²

Core	Latitude	Longitude	Depth (m)	CaCO ₃ (%)	Maximum preservation (cm)
ERDC 92 Bx	2° 13.5'S	156° 59.9'E	1598	83.6	26.5
ERDC 88 Bx	0° 02.9'S	155° 52.1'E	1924	88.2	21.5
ERDC 112 Bx	1° 37.5'S	159° 14.1'E	2169	84.3	23.5
ERDC 120 Bx	0° 01.0'S	158° 41.6'E	2247	85.0	26.0
ERDC 102 Bx	3° 36.3'S	161° 19.1'E	2306	87.1	17.5
ERDC 83 Bx	1° 24.1'N	157° 18.6'E	2342	83.0	23.5

ERDC 123 Bx	0° 01.3'S	160° 24.9'E	2948	83.1	26.5
ERDC 125 Bx	0° 00.2'S	160° 59.9'E	3368	82.8	21.5

Results from the first four and from the last four cores were pooled to derive the averaged signal in Fig. 1. Results from Core ERDC Bx 102 were rejected. Water depth is based on echo sounding, corrected for (assumed) regional differences in sound velocity.

where v_0 is the tracer signal, in our case oxygen isotope composition in ‰ PDB.

To test the efficacy of equation (1) (or its expansion) we can apply it to the ash data^{9,10}, where it will be seen that the saw-tooth-like frequency distributions of ash particles are readily converted to rectangular signal spikes, as expected. But, any noise in the record, that is, irregular excursions due to discrete burrowing, is immediately transformed into large erratic excursions. To avoid this it is necessary to collect several records of the same time interval, and to add them up in order to obtain a smooth average 'best' record.

Oxygen isotope record

Because of the considerable interest attaching to the climate and ocean dynamics of the past 20,000 yr, we have endeavoured to produce such an averaged oxygen isotope record for this period. Our cores are box cores from the western equatorial Pacific (see Table 1). The nine cores shown are well above the lysocline and are virtually free from dissolution effects, which distort the isotope record¹¹. The cores were sampled at closely spaced intervals, between 3 and 4 cm on the average. The isotopic composition of the planktonic foraminifer *Pulleniatina obliquiloculata* was determined by standard procedure, after establishing that the

isotopic signal of this species is similar to that of *Globigerinoides sacculifer*, in well-preserved sediment, except for an offset of 0.8‰^{11} . This offset reflects the fact that *P. obliquiloculata* grows its shell at somewhat greater depths than *G. sacculifer*, on the average.

Results of the determinations show a striking similarity of the oxygen isotope sequences in eight of the nine cores (see Fig. 1). Box core 102 does not follow the general pattern and is not considered further. Since all cores are from the same area, any idiosyncracies must be due to local disturbance.

We next average the eight acceptable sequences into one. Sedimentation rates are likely to differ somewhat, and isochrons must first be found, for proper addition. The exact dates of such isochrons are immaterial for this exercise.

We choose two such isochrons, besides the surface, for correlation. The first (13,000 yr b.p. according to ¹⁴C dating of Core 92 (ref. 11), is a point halfway between the late (isotopically light) segment of the high gradient transition from glacial to postglacial, and the segment of maximum preservation of the fine sand fraction (the preservation spike near 14,000 yr b.p.¹²). The second isochron (about 18,000 yr b.p.¹¹) is the point where the $\delta^{18}\text{O}$ values are presumed to be heaviest. The distance between the two isochrons in Core 92, which is ¹⁴C-dated¹¹ and in Core 112, where a very heavy isotopic value was obtained near 35 cm, was taken as a guide for determining where approximately this 18,000 yr b.p. level¹³ should be in the cores, in addition to the actual isotope determinations in each core.

The isochrons thus determined are shown in Table 2. A straightforward addition by core depth alone would yield a similar result: each core (except Bx 102) shows a small $\delta^{18}\text{O}$ minimum at the end of the steep transition segment, at almost identical depth, that is, near 20 cm. Our correlation procedure, therefore, besides being standard practice in deep-sea micropalaeontology, produces an acceptable match of the cores.

On the basis of this agreement as to depths in core (and not just sequence), we next construct two average isotope signals as a function of average depth with the $\delta^{18}\text{O}$ minimum centred on 20 cm (Fig. 1, two heavy lines). The first average signal is based on cores 92, 88, 112, and 120. The second is based on cores 83, 79, 123, and 125. Thus, the two average curves are derived completely independently. Their near-congruency is remarkable. We take this close agreement as further support for our correlation procedure. The median line between the two generalised signals (Fig. 1, fine line between two heavy lines) is our best estimate of a true oxygen isotope signal as would be recorded in an ideal core.

We consider this averaged signal to be more detailed and more reliable than any oxygen isotope record now available from deep-sea carbonates for this period. We realise also that this signal will have to experience some modifications as more data become available.

The result of applying our unmixing equation to this record is shown in Fig. 1. The reconstructed signal is represented by the shaded zone. The borders of the shaded zone show the possible amplitudes of the presumed original signal, for a mixed layer parameter m between 4 and 8 cm. This range for m has been established as reasonable for deep-sea sediment in general⁸ and also is indicated by unpublished results of closely spaced ¹⁴C

Fig. 1 Stacked and reconstructed oxygen isotope signal from eight box cores taken above the lysocline, on Ontong-Java Plateau. Heavy lines: results of two separate stackings, of four records each. Centre line between two heavy lines: overall average signal. Shaded area: approximate estimated shape of original signal, using unmixing equation $c_0 = c + c'm$. Outer bound (large amplitudes): $m = 8$ cm. Inner bound (small amplitudes): $m = 4$ cm. The age scale refers to the actual signal, not the reconstructed one. Fix points are 12,000 yr b.p. for the meltwater anomaly, 14,000 yr b.p. for maximum preservation, 18,000 yr b.p. for the glacial maximum, based on ¹⁴C dating of core ERDC 92^{11,12}. The ● represent an average isotope signal resulting from correlation by the preservation spike only (Table 1, last column) demonstrating the absence of bias in the combined isotope-preservation correlation procedure (see text).

	13 kyr b.p.										18 kyr b.p.	

Fig. 2 Oxygen isotope composition of *Pulleniatina obliquiloculata* in nine box cores from Ontong Java Plateau above the lysocline (~ 3,500 m). Decimal points indicate position of sampling midpoint. All values in $\delta^{18}\text{O}_{\text{‰}}$ PDB (negative, unless marked +). Stippled lines indicate estimated positions of two isochrons (~ 13,000 yr b.p. between (estimated) maximum anomaly of product [$e \times c$] and centre of maximum preservation; and ~ 18,000 yr b.p. at maximum value of $\delta^{18}\text{O}$).

dating of Core 92, by T. H. Peng. The larger m produces the larger amplitude, as seen from equation (1).

The resulting reconstructed signal, that is, the shaded field in Fig. 1, has some interesting features, the outstanding one being the pronounced $\delta^{18}\text{O}$ minimum (near 12,000 yr b.p.). One might argue that the amplitude of this minimum is partly due to our method of correlation, in which the isotope signal itself had one-half weight for determination of the 13,000 yr b.p. isochron. This objection, raised by N. J. Shackleton, in private discussion, is entirely justified. We have, therefore, re-done the correlation using only the centre of the preservation spike as a guide. The resulting average isotope signal is shown in Fig. 1, as a string of heavy dots. It is obvious that the outcome of an unmixing exercise on this signal would be quite similar to the reconstructed signal given.

In showing a pronounced $\delta^{18}\text{O}$ minimum near 12,000 yr b.p. and also in other details, our reconstruction resembles closely the raw oxygen isotope records found by Kennett and Shackleton¹⁴ and by Emiliani *et al.*¹⁵ in the Gulf of Mexico. Their signals are derived from cores with high sedimentation rates which are much less susceptible to distortion by benthic mixing than ours. Emiliani *et al.* date the prominent $\delta^{18}\text{O}$ minimum near 12,000 yr b.p., a date that agrees with ours and with the estimate by Kennett and Shackleton. Hence, we are reasonably confident that we are seeing a worldwide phenomenon, of which the Gulf of Mexico anomaly is a special regional manifestation. (Note that the age scale in Fig. 1

refers to the actual signal, not the reconstruction, so that the 12,000-yr date shown coincides with the original $\delta^{18}\text{O}$ minimum.)

A worldwide phenomenon

What is this phenomenon? The Gulf of Mexico results have been interpreted as showing an influx of meltwater from the Laurentide Ice Sheets^{14,15}. This influx would strongly decrease the $\delta^{18}\text{O}$ values of the upper water layer, and hence of the shells of the foraminifera living within it.

We propose that a similar effect may exist for the entire world ocean. Our interpretation supports the hypothesis of Worthington¹⁶, who postulated that the rapid influx of meltwater to the world ocean must have resulted in a low salinity upper water layer, forming a lid on the ocean. Below this lid, which prevented vertical mixing, CO_2 would have accumulated and this CO_2 enrichment would have led to increased dissolution of the shells of foraminifera on the sea floor¹⁶.

The increase of dissolution postulated by Worthington has been found, and occurs exactly at the point predicted¹². On renewed mixing, any deep-trapped CO_2 should have been released to the atmosphere. A rapid warming might be expected at this point. There is evidence that the warming at the beginning of the Holocene, which led to the Hypsithermal was very rapid^{17,18}. In our scenario, this warming event is the one recent geological analogue of the present large-scale release of industrial CO_2 to the atmosphere. Its course and its effects on the biosphere should hold great interest for future investigation.

This research was supported by the US NSF (grant OCE 75-04335) and by the Office of Naval Research (contract USN N00014-75-C-0152). The Stable Isotope Sediment Laboratory was set up with US NSF support (DES 75-04497, to W. H. Berger and M. Kastner) and with support from the Scripps Industrial Associates and from Chevron Oil, California. We thank E. Vincent for supervising sample preparation and for discussions. The box coring device was provided by R. R. Hessler, and G. Wilson assisted in taking the cores.

Plate boundary within Tjörnes Fracture Zone on northern Iceland's insular margin

Robert L. McMaster & Jean-Guy E. Schilling

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island, 02881

Paul R. Pinet

Department of Geology, University of Georgia, Athens, Georgia, 30602

The current North American-Eurasian plate boundary on Iceland's northern insular margin is defined. Overlapping rift zones and en echelon post-glacial volcanic eruptions oblique to the apparent transform direction of the Tjörnes Fracture Zone suggest that the fault is in a transient deformational stage.

ICELAND represents an anomalous segment of the Mid-Atlantic Ridge that remains unexplained by the simple elements of plate-tectonic theory. The abnormal build-up of the Iceland platform also coincides with the pronounced change of the ridge direction. Although the history of rifting over Iceland is complex, the zones of neovolcanic and tectonic activity now appear fairly well defined^{1,2}.

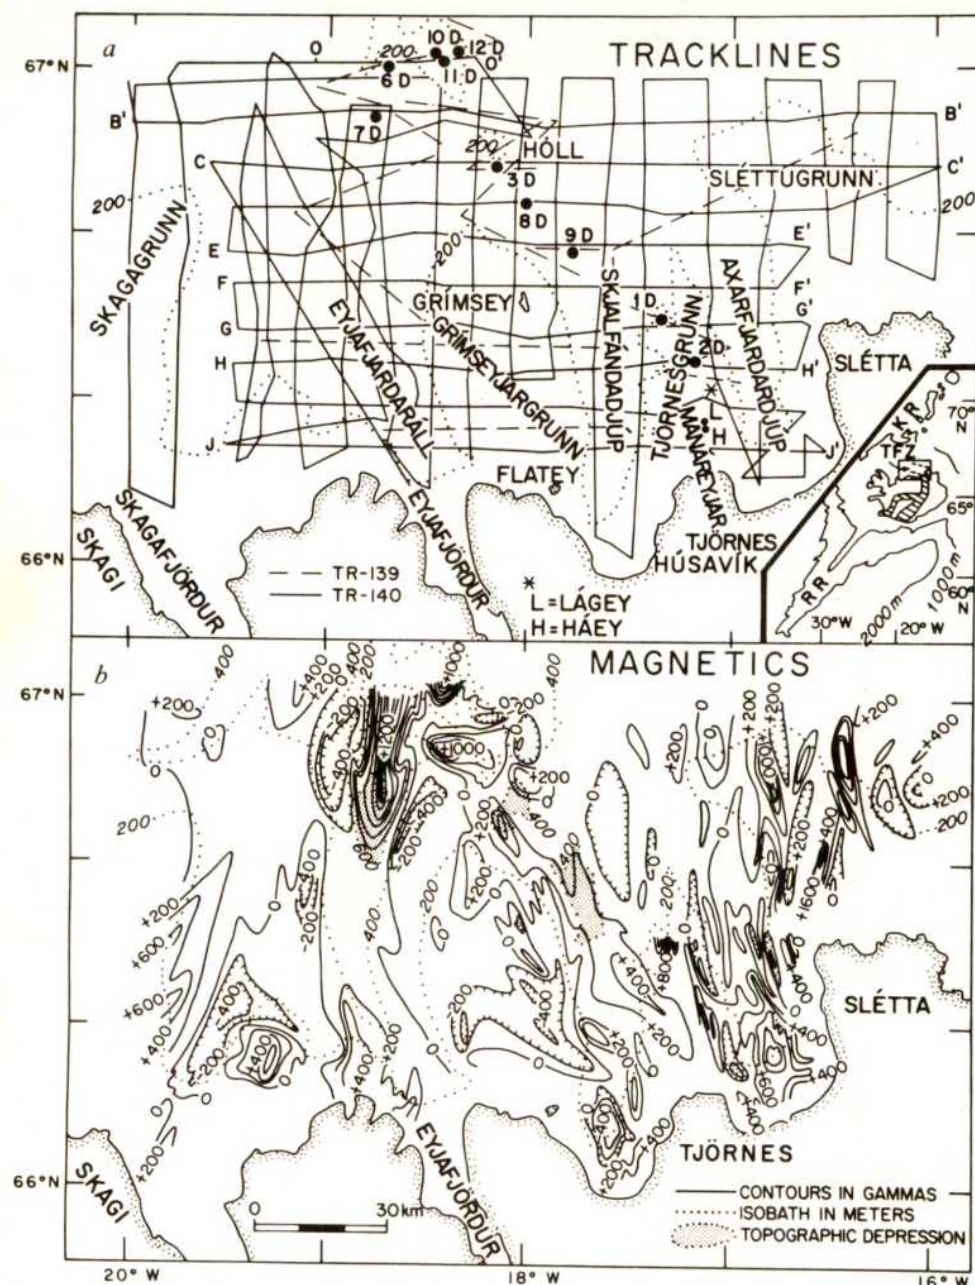

Fig. 1 Insular margin, northern Iceland; a, locations of R/V Trident's TR-140 tracklines and TR-139 tracklines and dredge stations; b, magnetic anomalies. On index map KR, Kolbeinsey Ridge; RR, Reykjanes Ridge; TFZ, Tjörnes Fracture Zone.

This report focuses on the offset zone between the Kolbeinsey Ridge^{3,4,5} and the north-east neovolcanic zone (NENZ) (ref. 6) of northern Iceland's insular shelf, commonly referred to as the Tjörnes Fracture Zone (TFZ) a right-lateral transform fault^{3-5,7-9} (Fig. 1a). Not only is the existence of the transform fault questioned^{2,10} but proponents^{4,5,8,9} acknowledge that topographic expressions paralleling the transform direction fail to control the offset zone.

We report here new evidence derived from a detailed field investigation involving bathymetry, magnetics, seismic reflection and rock dredging on the insular margin. The survey was conducted during the University of Rhode Island's R/V Trident cruises 139 and 140, in summer of 1973. The ship's tracks shown in Fig. 1a were controlled by satellite navigation.

Our results reveal that morphologically and tectonically the TFZ is dominated by three N-S striking lineaments, namely Kolbeinsey Ridge—Eyjafjardaráll Trough Complex (KRETC), Kolbeinsey Ridge—Skjálfandadjúp Trough Complex (KRSTC) and the Axarfjardardjúp Trough. These features display remarkable continuity across the shelf and overlap each other towards the north-west. The three troughs are distinguished by faulting with post-glacial volcanic activity occurring within

both Eyjafjardaráll and Skjálfandadjúp rifting zones but not along their entire lengths (Fig. 2). In contrast the zones of recent volcanic activity are arranged in a NNW-SSE *en echelon* fashion from the Kolbeinsey Ridge towards the axis of the NENZ (Fig. 2) and thus do not imbricate significantly as the rift zones do.

Kolbeinsey Ridge—Eyjafjardaráll Trough Complex

The KRETC is governed by N-S dip-slip faulting. On the north the ridge is symmetrical, remarkably regular, and broken only by the small persistent rift valley that is offset westward from the crestal axis (Fig. 3, profile O). A strong positive magnetic anomaly is aligned along the valley trend, flanked on the west by a weaker but equally well-defined negative anomaly (Fig. 1b). Small eruptive fissures typify the graben's floor which is shown by dredging to consist of fresh pillow basalts (Fig. 2, Table 1, station 6 and 7). Onlapping sediments thicken away from the axis as expected for normal spreading ridges. Southwards the character of the ridge is altered significantly: the elevation decreases as the width increases even though the

Table 1 TR 139 rock dredging across Tjörnes Fracture Zone

Station	Latitude and Longitude	Depth (m)	Feature	Recovery	Inference
1D	66°30.5'N 17°20.5'W	65–80	Flat-topped seamount; NW Tjörnesgrunn	Fresh glassy pillow basalt fragments	Post glacial submarine eruption (possibly 1868)
2D	66°25.5'N 17°10'W	16–25	Mánareyjar ridge crest; Lágey	Poorly sorted palagonitized tuff fragments	Not far from source vent
3D	66°48.5'N 18°09'W	180–205	Kolbeinsey Ridge— Skjálfandadjúp Trough Complex: Höll Seamount	Rounded and jointed cobbles; oxidised scoriaceous vesicular basalt	Subaerial or very shallow depth submarine eruption, near vent, wave erosion and subsidence—post glacial
6D	67°00.5'N 18°42.5'W	270–310	Kolbeinsey Ridge— Eyjafjardaráll Trough Complex—eruptive fissure on graben floor	Fresh glassy pillow basalt	Typical submarine ridge eruption—post-glacial
7D	66°54.5'N 18°46.5'W	400–410	Kolbeinsey Ridge— Eyjafjardaráll Trough Complex—eruptive fissure on graben floor	Fresh glassy pillow basalt with brown crust	Typical submarine ridge eruption—post-glacial
8D	66°44.5'N 18°00.5'W	340–350	Kolbeinsey Ridge— Skjálfandadjúp Trough Complex—small graben	Tuff fragments, 3 small pebbles of massive basalt, indurated balls of mud with glass shards (one surrounded with a small film of lava)	Subaerial volcanic material with some recent submarine volcanic activity
9D	66°38.5'N 17°47'W	180–210	Kolbeinsey Ridge— Skjálfandadjúp Trough Complex—isolated seamount within graben complex—with sediment disturbance	Large vesicular basalt, slightly glassy—small fresh highly vesicular pillows with palagonite crust; rounded cobbles—small fist-size grabbo nodules	Post glacial subaerial or shallow submarine eruption—inconclusive
10D	67°02.5'N 18°28.5'W	65–80	Kolbeinsey Ridge— Skjálfandadjúp Trough Complex. Large flat-topped volcano with two distinct terraces at 55 m and 90 m	0.3 m rounded vesicular basalt	Post glacial subaerial eruption—wave erosion
11D	67°01.5'N 18°26'W	90–100	Same feature as 10D	Rounded vesicular basalt; banded tuff, near vent, few erratics	Post glacial or inter-glacial subaerial eruption, near vent, wave erosion, subsidence
12D	67°02.5'N 18°22'W	90–100	Same feature as 10D (90 m terrace)	Cobbles and pebbles of vesicular basalt; 1 limestone fragment	Post glacial or inter-glacial subaerial, volcanic island; surf zone type deposit

acoustic basement configuration and sediment accumulations remain symmetrical about the ridge axis (Fig. 3, profile B). The subsiding effect serves to promote fracturing. The south-eastern ridge extension, marked by peaks and small grabens maintains its ridge profile but the southern ridge branch gradually changes to a linear depression. In the Eyjafjardaráll Trough at 66°40'N, the coincidence of intersecting faulting, the limit of axial magnetic stripes and sediment deposits⁵ coupled with the site of the closed 40 mgal free-air gravity anomaly contour¹¹ define a structural-volcanic discontinuity (Fig. 2). Southwards the trough is bordered and apparently controlled by N–S dip-slip faults which at the trough's shoreward end bend toward the SE to join the WNW Húsvík fault trend⁹. Sediments more than 0.3 s thick fill the trough and no evidence of volcanic activity is observed. Thus the 66°40'N structural-volcanic discontinuity clearly represents the southernmost extent of spreading and rifting in the TFZ which is in direct continuity with the present Kolbeinsey Ridge spreading axis.

Kolbeinsey Ridge–Skjálfandadjúp Trough Complex

The SE curving KRSTC shows numerous dip-slip faults that follow the trend (Fig. 2). The south-eastern ridge extension contains a series of discontinuous volcanic peaks, including Höll, and small grabens along the trend that disappear at 66°49'N. Only the south-eastern end of a negative anomaly

band is evident due to its disruption by a strong positive anomaly west of Höll (Fig. 1b). Overlapping sediment deposits typify the extension's eastern flank (Fig. 3, profile C). The adjoining Skjálfandadjúp's borders are controlled by normal faulting except over its southernmost reach where downwarping seems to govern its western flank (Fig. 2). A distinct NW–SE trending positive anomaly can be traced from Höll to Tjörnesgrunn (Fig. 1b). The north-western half of this anomaly overlies the trough's floor. East and south of Grímsey the trough turns to the south but the positive anomaly maintains its SE strike, cutting across the trough's eastern wall and intersecting the western flank of Tjörnesgrunn at a high angle. The most intense faulting occurs north, east and south-east of Grímsey (Fig. 2). The direction and style of faulting fail to support the presence of a major WNW right-lateral strike-slip fault in this area previously inferred¹². We also feel that the distribution and precision of earthquake epicentre locations are insufficient to resolve the two interpretations (Fig. 2). Furthermore the trough's northern section contains numerous submarine eruptive features where little or no sediment is accumulating (Fig. 2, Table 1, stations 8 and 9). It is clearly evident that volcanic activity in the Skjálfandadjúp rifting zone is restricted to the segment north and north-east of Grímsey. Both subaerial and fresh submarine volcanic products, apparently post-glacial, are present. Rocks from Höll Peak and southwards are dominated by vesicular and scoriaceous basalts rounded by wave action suggesting subsidence of the ridge extension (Fig. 2,

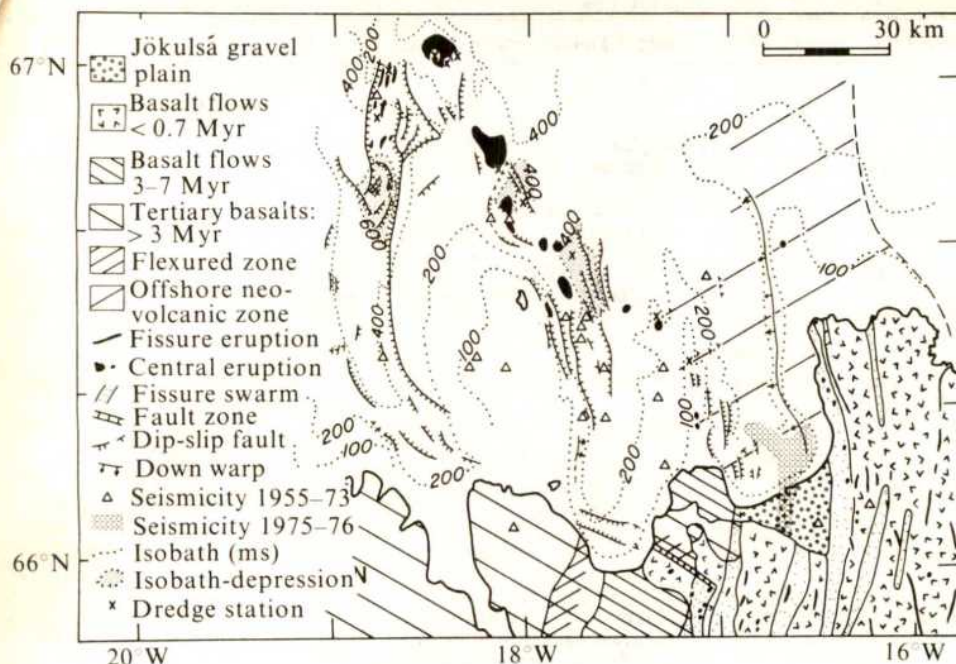

Fig. 2 Summary geology map. Earthquake epicentre locations (refs 13, 21); 1964-73 epicentres from Preliminary Determination of Epicenters Monthly Listing published by US Coast and Geodetic Survey and successor organisations through 1972 and jointly by NOAA/USGS thereafter.

Table 1, stations 3, 10, 11 and 12). South of 66°31'N no recent volcanic activity is observed as sediment covers the trough's floor reaching a thickness of 0.13 s towards the coast.

Axarfjardardjúp Trough

This trough is a downwarp modified by faulting, rifting and volcanism (Fig. 2). The predominant direction of the dip-slip faults is parallel to the trough's long axis. Normal faulting is associated with the eastern flank of the apparently older Mánareyjar volcanic chain and can be traced southwards to the Tjörnes Peninsula's eastern border scarp¹³. The trough's magnetics show a series of narrow, elongated anomalies which differ markedly from the Kolbeinsey Ridge anomaly bands (Fig. 1b). Notably the western edge of this anomaly series strikes NNW-SSE and diagonally crosses the Tjörnesgrunn trend⁶. Recent undeformed sediments up to 0.1 s thick, partially or completely cover the trough's floor (Fig. 3, profiles H and J). Although no morphological indications of volcanism are manifest and no search for evidence of recent volcanic activity was possible due to time limitations, pre-depositional rifting is distinctly revealed at the trough's southern end alongside Tjörnes Peninsula (Fig. 2 and Fig. 3, profile J). Moreover, since our survey's completion, significant recent rifting¹² is reported in the same part of the trough covered by our seismic reflection lines but lies immediately eastward of the pre-depositional rift zone. Hence recent rifting occurs in the offshore NENZ⁶ and is not found on the Mánareyjar chain as indicated previously².

Subdued shelf ridges

The three tectonic trends discussed above are separated by Sléttugrunn, Tjörnesgrunn and Grímseygrunn (Fig. 1a). On the east Sléttugrunn is the northward lobate projection of Slétta Peninsula (Fig. 1a). It is characterised by the same magnetic anomalous pattern observed in the Axarfjardardjúp Trough (Fig. 1b). Alignment of these anomalies with fissure swarms on land as well as their general N-S strike and high magnetic intensity suggest an offshore continuation of the NENZ (ref. 6). Some volcanism is revealed by the presence of a single cone and apparent flows, indicated by the lack of sub-bottom penetration, that cover the surface immediately seaward of the Slétta Peninsula but no seismicity is reported⁹ (Fig. 2). Thus volcanically and tectonically most of Sléttugrunn may represent a presently dormant zone.

Tjörnesgrunn is a tapering N-S submarine extension of the Tjörnes Peninsula that includes the Mánareyjar volcanic

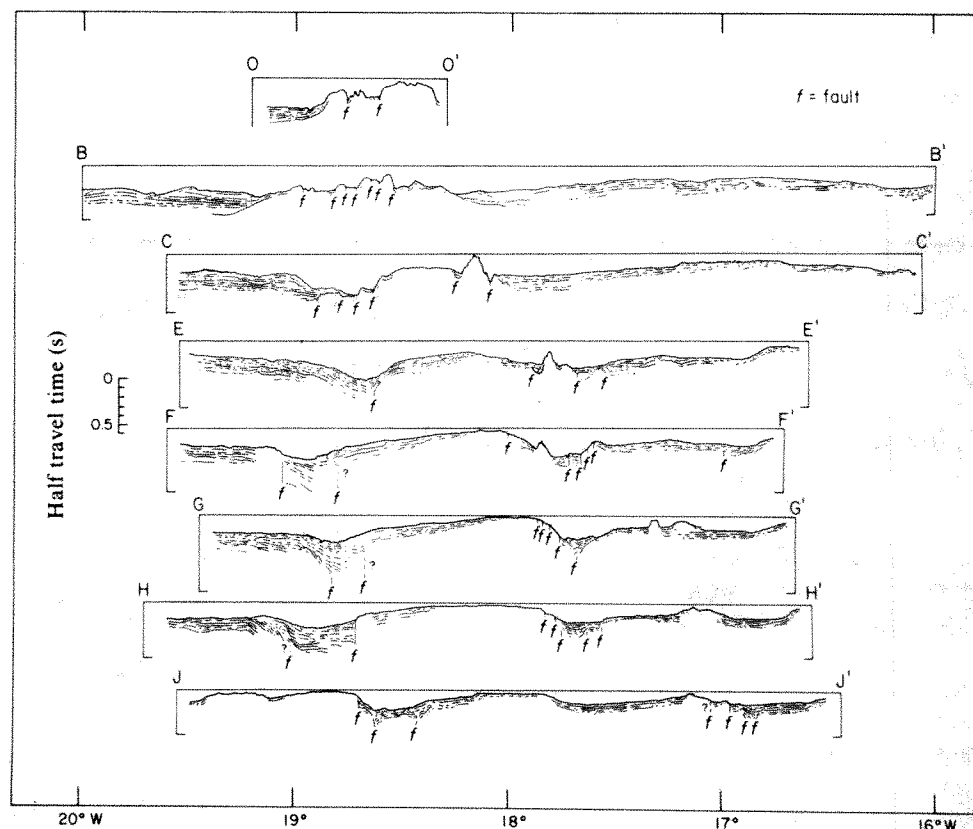

chain (Fig. 1a). Its eastern flank, partly fault controlled, is steeper and more irregular than its western flank. The western edge of the magnetic anomaly series that distinguishes Axarfjardardjúp and Sléttugrunn, passes beneath the ridge's outer reach (Fig. 1b). No evidence of recent submarine volcanic activity is encountered along the N-S Mánareyjar ridge crest, which is probably formed of relatively older subaerial volcanics. Only palagonitized tuff and interbedded vesicular basalt pebbles are dredged from the crest at the ridge north of Lágey (Fig. 1a and Table 1, station 2). The material is similar to that found on Háey, or overlapping the grey basalt flow of Lágey islets. Near the NW end of Tjörnesgrunn, however, (Fig. 1a, Table 1, station 1) very fresh glassy vesicular pillow basalts is recovered from a flat-topped seamount. The seamount definitely represents a recent submarine eruption at very shallow depth, perhaps representing the 1868 volcanic activity reported in Icelandic history. This volcanism, lying along the NENZ's western border may suggest another small rift segment linking the general NNW *en echelon* pattern of rifting and latest volcanic activity that occurs in the Skjálfandadjúp.

Grimseyjargrunn is a tabular block that shows no internal acoustic reflectors (Fig. 1a and Fig. 3, profiles F, G, H and J). The block is negatively magnetised crust except for its northern and southern edges which display weak positive anomalies (Fig. 1b). The ridge's northern and eastern walls descend steeply into Skjálfandadjúp while its western flank with on-lapping sediments slopes gently westwards into Eyjafjardaráll. The westward dip is the same as that reported for Tertiary flood basalts of the adjacent coastal area⁹. Grimsey Island, laying atop of Grimseyjargrunn, also consists of SW dipping plateau basalts with a suggested age younger than mid-Gauss⁹.

Húsavík faults

The Húsavík faults⁹ are extended west-north-westward across Skjálfandadjúp's southernmost reach (Fig. 2). Between Húsavík and Eyjafjardaráll, the axis of a gravity low¹¹ lies immediately north of the apparent trace of the offshore fault zone. At the southern end of Eyjafjardaráll, the centre of the gravity low is elongated WNW-ESE and the trough's faults bend towards the south-east. These deviations from the N-S trend may reflect strike-slip dislocations along the seaward extent of the Húsavík faults between 4-1 Myr age⁹. Thus the Húsavík fault zone is unrelated to present rifting of the Mid-Atlantic Ridge as activity along these faults is believed to have diminished about 1 Myr ago¹⁴.

Fig. 3 Line drawings of selected seismic reflection profiles. For locations see Fig. 1a. f, Fault.

Discussion

From these preliminary results, we infer that no transverse tectonic features common to transform faults^{15,16} are recognised over the TFZ with the exception of the Húsavík faults which are believed to be presently inactive and unrelated to the plate boundary. Instead the TFZ is characterised by three distinct and overlapping tectonically active zones associated with the KRETC, KRSTC, and Axarfjardardjúp Trough (NENZ). Seismicity shows no simple and direct relationship with these active zones except for the post 1973 earthquakes at Axarfjardardjúp's southern end¹² (Fig. 2). Recent volcanic activity along eruptive fissures between the Kolbeinsey Ridge and NENZ occurs in NNW-SSE *en echelon* manner (Fig. 2) and defines the most recent plate boundary between Eurasia and Greenland. Practically no overlap of volcanic activity is found except perhaps immediately south of 67°N where Eyjafjardaráll and Skjálíandadjúp connect with the Kolbeinsey Ridge. The *en echelon* arrangement of recent eruptive fissures is further corroborated by magnetic anomaly lineaments and to some extent by the distribution of recent earthquake epicentres in Axarfjardardjúp Trough¹³.

The surface structural character of the TFZ revealed in our survey may be compared profitably with the transform tectonic expressions produced by a simple experimental clay model for the transient stage of discontinuous deformation¹⁷. During this stage the azimuth of fault traces develops oblique to the offset direction. Clear similarities are found but discrepancies are also evident. Analogies include: (a) the assumed displacement direction being roughly 65° with respect to the normal faults of the Kolbeinsey Ridge and Axarfjardardjúp Trough (NENZ); (b) *en echelon* dip-slip faults and eruptive fissures in Skjálíandadjúp striking 30°–40° relative to the presumed displacement trend; (c) intersecting rift zone and oblique fault systems forming crude diamond-shaped blocks in the Kolbeinsey Ridge-Eyjafjardaráll Trough transition. Significant dissimilarities are that *en echelon* oblique faults are not distributed uniformly across the assumed displacement zone, major strike-slip movement is not documented along these faults although near Grimsey strike-slip motion has been determined recently from a fault plane solution¹² and no intersecting fault

pattern is found where the inferred activity meets the NENZ. Despite these discrepancies we believe that the arrangement of volcano-tectonic features within the TFZ is best explained by discontinuous transformation as expressed by the clay model¹⁷. Perhaps the transient stage is somewhat mature judging from the 30°–40° angle that faulting and eruptive fissures form with the presumed displacement of the transform fault.

These types of transient or leaky transform faults are also noted south of Iceland, the Afar, and south of the Azores Platform at 37°N (refs 17, 18). The three areas occur at the loci of proposed mantle plumes and major directional changes of the mid-ocean ridge. Independently, Burke *et al.*¹⁹ suggest that mid-ocean ridges located near mantle plumes will tend to jump back over the plume during a transient stage thus generating multiple spreading ridge axes and consequent fracture zones, overlapping to some extent in space and time. Recent detailed spatial and temporal analyses of active rift zones throughout Iceland^{2,20} seem to indicate such rift jumping. Our proposed transient stage of discontinuous deformation for the TFZ, therefore, seems to be consistent with such a model. Further Walker's² conjectured *en echelon* active rift zone configuration for the TFZ, based on meagre data, is essentially confirmed.

Finally, tensional fissures removed from the major plate boundary are clearly documented in the clay model experiment for the transient stage of discontinuous deformation¹⁷. Therefore we suggest that the active eruptive centres along Sléttá's western coast (Fig. 2) which remain unexplained² as well as the recent linear submarine volcanic zone of the KRETC are identical features. As such these kinds of eruptive fissures may have a similar origin to that proposed for the Vestmann Islands¹⁷. In these cases the fissures are considered to lie along prolongation of normal faults that extend into the plate for limited distances on diagonally opposite sides of the offset.

We acknowledge support (NSF Grant DES 72-01705) and are grateful to Iceland's National Research Council for permitting the field work to be undertaken.

Amino-terminal fragments of *Escherichia coli* *lac* repressor bind to DNA

Thomas M. Jovin, Norbert Geisler & Klaus Weber

Max-Planck Institut für Biophysikalische Chemie D-34 Göttingen, FRG

The N-terminal fragments (residues 1–51 and 1–59) obtained by selective tryptic cleavage of native lac repressor retain the ability to bind DNA. These fragments (headpieces) are monomeric and form complexes which resemble those of tetrameric repressor with non-operator DNA. But, they do not show the high specificity of repressor for operator sequences. The DNA binding has been demonstrated by filter-binding assay as well as in solution using absorption, circular dichroism, and fluorescence measurements.

There is overwhelming genetic and biochemical evidence to indicate that the integrity of the amino-terminal segments of the *Escherichia coli* *lac* repressor subunits is a necessary requirement for the weak binding to non-operator DNA as well as the highly specific and strong binding to operator DNA^{1–6} (for reviews and discussion, see refs 7–9). Geisler and Weber¹⁰ have reported the selective cleavage by trypsin of the N-terminal region of repressor at Arg₅₁ and Lys₅₉ so as to liberate approximately equal amounts of 'short' and 'long' headpiece peptides (designated here as SH and LH) comprising residues 1–51 and 1–59. The tetrameric core no longer binds DNA (ref. 3) but the headpiece preparations retain affinity for phosphocellulose and DNA–cellulose, a criterion for nonspecific DNA binding^{7,9}.

The aim of this study was the initial characterisation of the DNA-binding properties of the two headpiece fragments and their correlation with known features of native repressor. The presumption that the characteristics of headpiece are related to those of the parent repressor and are thus biologically relevant is based on the following considerations: (1) isolated headpiece possesses secondary structure revealed by circular dichroism¹⁰. (2). The pattern of susceptibility to trypsin digestion is the same for isolated headpiece and the corresponding region in native repressor. Thus, in 1 M Tris-HCl, pH 7.5, 30% glycerol, repressor is cleaved so as to generate headpiece but the latter is not susceptible to further digestion¹⁰. We have established that the isolated headpiece is also resistant to trypsin in the same conditions (data not shown). In 0.05 M Tris buffer, however, both isolated headpiece and the corresponding region in intact repressor rapidly undergo further proteolysis to peptides (data not shown). (3). The capacity of repressor to bind DNA nonspecifically is transferred to β -galactosidase in chimaeric molecules produced by certain gene fusions between the *i*- and *z*-genes of the *lac* operon⁶. These molecules carry about 59–80 residues of the N terminus of repressor. Further evidence for the close relationship between the properties of the isolated headpiece and those of native repressor was obtained in the present study.

In interpreting these findings, one should note the close correlation between the operator-specific and the nonspecific modes of binding of *lac* repressor to DNA and the important role ascribed to the sequence-independent interactions in the regulation of repression^{6–9,11}.

Determination of DNA binding by filter assay

The two headpieces LH and SH can be separated on DNA–cellulose columns (Fig. 1a). SH elutes before LH, as might be expected due to its smaller size and charge. Both fragments are active in binding assays based on the retention of protein–DNA complexes on nitrocellulose filters (Fig. 1b). The markedly sigmoidal binding isotherms denote the existence of real (or apparent) co-operativity, a feature not seen with native repressor. While the binding of DNA is quantitative at high concentration of either headpiece, the points for 50% retention and the corresponding slopes differ markedly (0.8 μ M and 3 μ M for LH and SH, respectively). The mixed headpiece preparation shows an intermediate behaviour consistent with the superposition of LH and SH properties, the former being dominant.

Additional features revealed by the filter assay are given in Table 1. In standard conditions, various natural and synthetic DNA's are bound in a similar fashion. Thus, headpiece does not demonstrate a sequence-specific (operator) interaction with DNA, in contrast to the parent repressor. Denaturation of the DNA slightly potentiates binding by headpiece while fragmentation by sonication diminishes it only to a limited degree (note also the large difference in chain lengths between the phage DNA and poly d(A–s⁴T) used in Table 1). Salt manipulations lead to complex and somewhat DNA-dependent effects. Eliminating Mg²⁺ or raising the KCl concentration increases binding at low headpiece concentrations but reduces the maximal extent of retention, especially in the case of phage DNA. One is undoubtedly perturbing the thermodynamic¹⁷ and kinetic⁷ parameters governing the formation of the binary complex and/or its interactions with the filter. Finally, the kinetics of association and dissociation are relatively rapid. With poly d(A–s⁴T) and headpiece at 50 nM and 2.5 μ M, respectively, a filterable complex is formed within 10 s (a value which only sets a lower limit for k_{on} of about 10⁴ M^{–1} s^{–1}). Similarly, challenging a preformed complex with an 100-fold excess of non-radioactive poly d(A–s⁴T) leads to dissociation within seconds. Taken together, these data establish that the headpiece of *lac* repressor possesses the inherent property to bind DNA and that the observed phenomena are not due to contamination with residual functional repressor.

Spectroscopic measurements using poly d(A–s⁴T)

Four of the eight tyrosine residues in each repressor subunit are located in the N-terminal region (residues 7, 12, 17 and 47) (ref. 16). Genetic analysis of repressor mutants has shown that Tyr₁₇ is essential for specific operator binding¹⁸. The spectral properties of the tyrosines are particularly suitable for study since no other chromophoric amino acid side chains are present in the headpiece. Figure 2A(a) shows the absorption spectrum of LH which corresponds closely to that of unionised unperturbed (exposed) tyrosine. Thus, the buried and ionised (or hydrogen-bonded) tyrosine residues observed in intact repressor by ¹⁹F nuclear

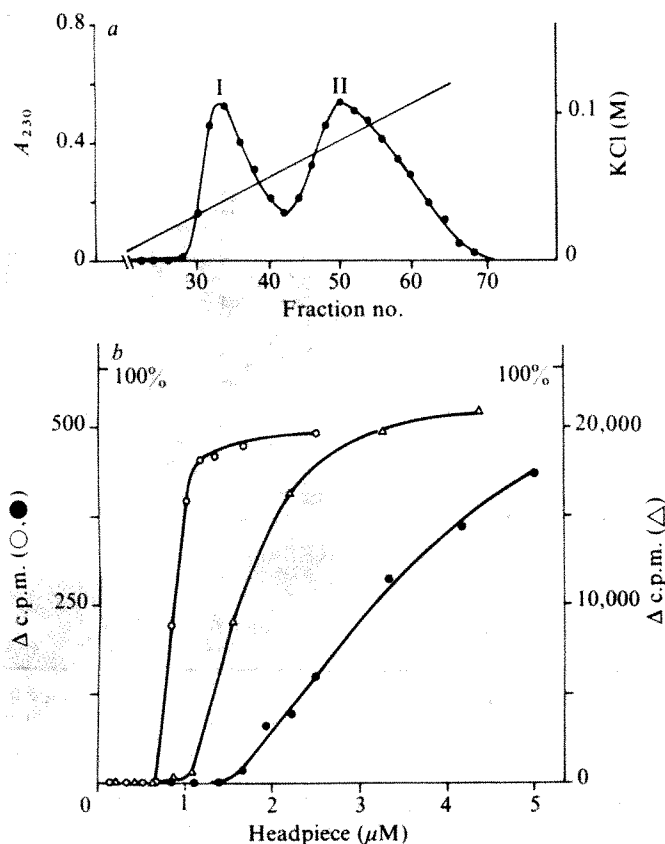

Fig. 1 Purification and DNA-binding properties of *lac* repressor headpieces. *a*, Separation of LH (long headpiece: residues 1-59) and SH (short headpiece: residues 1-51) on a DNA-cellulose column. Tryptic digests of repressor were prepared and purified by chromatography on Sephadex G-150 and G-25 according to Geisler and Weber¹⁰. The headpiece mixture was applied to a native calf thymus DNA-cellulose column¹² equilibrated with 50 mM Tris-HCl, pH 7.8 (4 °C), 1 mM EDTA, 5% glycerol and eluted with a 300 ml linear gradient of buffer containing 0-0.15 M KCl. Peaks I and II were identified as SH and LH, respectively, by amino acid analysis and C-terminal determination with carboxypeptidase B. The molecular weights of SH and LH are 5,615 and 6,395, respectively, from the amino acid composition. *b*, DNA binding by the two headpiece preparations and their unfractionated mixture. Slight modifications of the standard assay¹³ for the operator binding activity of repressor were used to increase retention and reproducibility: the 25-mm Millipore HAWP (0.8- μ m pore size) filters are supported on a glass holder, the outlet of which is filled with liquid and attached to a peristaltic pump. The binding buffer (BB) (0.6 ml) contained 10 mM KCl, 10 mM Tris-HCl, pH 7.4, 3 mM magnesium acetate, 0.1 mM EDTA, 5% dimethyl sulfoxide (DMSO), 0.1 mM dithiothreitol (DTT), and 50 μ g ml⁻¹ BSA. ³²P-labelled λ phage DNA (see Table 1) was present at a nucleotide concentration of 0.9 μ M (specific activity 1300 c.p.m. nmol⁻¹ in the case of LH and SH, 40,000 c.p.m. nmol⁻¹ in the case of the mixture). After addition of protein and incubation at about 25 °C for 30 min, 0.58 ml was filtered together with 0.5 pre- and post-washes of FB (filtering buffer, same as BB but lacking BSA and DTT) at a constant rate of 1 ml min⁻¹. The air-dried filters were counted in a scintillation counter. The background level of DNA binding to the filter was 2-3% and the 100% retention points (indicated on the ordinates) were calculated from aliquots of the DNA stock solution applied directly to the filters. Long headpiece LH (O), short headpiece SH (\bullet), and an approximately equimolar mixture (Δ).

magnetic resonance (NMR) spectroscopy¹⁹ are most likely in the core of the molecule. The accessibility of the amino-terminal tyrosines of native repressor (residues 7, 12, and 17) has also been established in iodination studies²⁰.

The synthetic polynucleotide poly d(A-s⁴T) was selected for further physical measurements because of its unique spectral properties¹⁵. The thioketo substitution in the position 4 of thymidine produces a strong absorption band in the near ultraviolet (Fig. 2A(b)), well isolated from the protein spectrum, and it also makes possible the efficient photoaffinity labelling of protein-nucleic acid complexes²¹. Poly d(A-s⁴T) forms a helical

structure with Watson-Crick base pairing and features intermediate between the C and D conformations. The pitch height and axial rise are about 10% greater than in the case of poly d(A-s⁴T) (W. Saenger, personal communication). Poly d(A-s⁴T) has been used in studies of *lac* repressor analogous to those described here for the headpiece (T.M.J., in preparation).

The binding of headpiece (LH) to poly d(A-s⁴T) results in altered absorption spectra (Fig. 2B). Hypochromic changes are seen in the s⁴T (360 nm) and, possibly, the dA (260 nm) regions. These cannot be attributed to a disruption of the DNA helix since the latter process leads to a hyperchromic blue shift¹⁵. The sign (positive) and positions of the peaks in the difference spectrum below 300 nm are strongly suggestive of perturbations in the tyrosine spectra, such as from ionisation (or hydrogen-bonding) of the phenolic OH²² or transfer from an aqueous environment to one of higher refractive index²³ (for example, through stacking interactions). If we attribute the change at 286 nm exclusively to tyrosine ionisation and assume that 50% of the headpiece is bound (from data in Fig. 4), then the observed magnitude would be compatible with the complete ionisation of two of the four

Fig. 2 Absorption and difference absorption spectra of repressor headpiece LH and poly d(A-s⁴T). *A*, Absorption spectra of *a*, 12 μ M LH and *b*, 51 μ M poly d(A-s⁴T) at 20 °C in BB buffer lacking BSA and DMSO. The instrument was a Cary 16. The LH spectrum is 10-fold expanded for clarity. The extinction coefficients for headpiece, based on amino acid analysis, are 4,800 M⁻¹ cm⁻¹ and 5,000 M⁻¹ cm⁻¹ at 280 and 276 nm. ($A_{280}^{1\%} = 7.6$), in agreement with corresponding values for tyrosine. The maxima of the DNA are at 347 and 263 nm and of the protein at 276 nm (minimum at 245 nm). *B*, Difference spectrum between the mixed and unmixed DNA and protein solutions. Tandem cuvettes with 0.438-cm path length in each compartment were used in both sample and reference beams. The solutions shown in (*A*) were used. The difference spectrum was obtained after mixing the sample cuvette. The maxima are at 230 and 286 nm and the minima at 266, 330, and 361 nm. The latter peak corresponds to a 2% decrease in absorbance. The peak at 286 nm represents a 37%, or a 4% increase if referred to the protein or DNA contributions alone, respectively. Isosbestic points are at 255, 273, and 307 nm. The difference spectrum in this and other experiments was virtually abolished by addition of 0.2-0.4 M KCl. The difference spectrum with the same concentration of SH was similar but 30% lower in magnitude.

Assay conditions were as in Fig. 1 except that half volumes were sometimes used. The binding at pH 8.6 was 20% lower at saturation than at pH 7.4 and 8.0. Labelled DNA's were obtained by induction and purification of phage DNA¹⁴ or synthesised by *E. coli* DNA polymerase I and extracted with sodium dodecyl sulphate and chloroform-isoamyl alcohol. The specific activities in c.p.m. nmol⁻¹ and background levels in the filter retention assay in % are given in parentheses: ³²P- λ *plac*: [*lac*, *pro*]₂ (λ Cl₈₅₋₈₇-*plac*5i⁻o⁺z⁺y⁻a⁻), strain BMH 782 (10³-10⁴, 1-5); ³²P- λ : W8 (λ Cl₈₅₋₈₇) (10⁴, 1.5); poly d(A-s⁴H-T) (5000, 4), poly d(³²P-A-s⁴T) (10³-10⁴, 3-6). The phage DNA's with or without the *lac* operator have chain lengths of 48,000 compared to 100-200 base pairs for poly d(A-s⁴T). Saturating concentrations of headpiece bound at least 6 nmol of phage DNA and up to 2 nmol of poly d(A-s⁴T). Denaturation in expt 5 was for 2 min at 100 °C. Sonication in expt 6 was for 10 min and led to an approximately 80% reduction in the native molecular weight.

*The additions were made only to BB except in expt 7 in which they were added to FB as well.

†The headpiece preparation was a mixture of SH and LH. There is an uncertainty of about 10% in the concentrations given for different experiments.

‡The corresponding value for native DNA was 1.3%.

§The numbers in parentheses correspond to parallel experiments with 0.17 nM native *lac* repressor.

||*i*^{-d} constitutive mutant with Val₉ replaced by isoleucine⁹. The tetrameric repressor does not bind to operator and shows a reduced affinity for phosphocellulose from which it is inferred that nonspecific DNA binding is impaired as well⁹. The headpiece isolated from another *i*^{-d} mutant repressor AP309 (Ser₁₆→Pro) binds normally to phosphocellulose¹⁰ and functions like the wild-type molecule in our filter retention assay.

tyrosines in the headpiece on binding to poly d(A-s⁴T). The isosbestic points are similar to those reported in model oligopeptide studies²⁴ in which various physical methods have provided evidence for both kinds of interactions between tyrosine side groups and DNA (ref. 24 and references therein). The difference spectra are abolished by added salt (0.2 M), attesting to the reversibility of complex formation. This finding is also in agreement with the ionic strength dependence of both the specific and nonspecific binding of repressor to DNA²⁵.

Poly d(A-s⁴T) has a circular dichroism (CD) spectrum with pronounced Cotton effects in the near ultraviolet (Fig. 3A(b)). The binding of headpiece leads to a positive displacement of the entire spectrum extending down to 265 nm, below which the protein contribution is dominant¹⁰. Native repressor produces similar effects. The titration of (mixed) headpiece with the synthetic DNA yields an apparent stoichiometry *n* of ≤10-14 basepairs per headpiece molecule (Fig. 3B). As in the case of absorption, the perturbation of the CD spectrum is incompatible with a denaturation of the DNA (which gives rise to decreased ellipticity at 340 nm). It is more probable that changes in helical parameters, also seen in the binding of repressor to poly d(A-s⁴T)^{27,28}, are involved⁷.

The luminescence properties of headpiece can also be exploited in combination with poly d(A-s⁴T). The excitation and emission spectra of headpiece are very similar to those of free tyrosine (Fig. 4A). Addition of poly d(A-s⁴T) leads to extensive quenching, the extent of which depends on the polynucleotide-to-headpiece ratio (Fig. 4B). The quantitative evaluation of such data is complicated by the phenomenon of excluded binding²⁶ especially in conditions of protein excess. A reciprocal titration is shown in Fig. 4C; in this case, the DNA is initially in excess and the parameters obtained (especially the dissociation constant *K*) should correspond to binding with minimal interaction between headpiece molecules (*K* > 10 μM , *n* ≤ 12, and the quenching is about 50%).

Discussion

The quenching of tyrosine fluorescence by poly d(A-s⁴T) could be due to hydrogen-bonding and proton transfer in the excited state³⁰, stacking interactions^{24,30}, and/or energy transfer to the bases^{30,31}. The latter process would be favoured by the spectral overlap between tyrosine emission (Fig. 4A) and 4-thiothymidine absorption (Fig. 2A). Many models for the operator-specific interaction of *lac* repressor and its amino terminus with DNA have discussed hydrogen-bonding and/or hydrophobic (intercalative) contacts between tyrosine side groups and the edges of bases exposed in the DNA grooves⁷. Structural features of the protein which have been proposed include protrusions¹, β structure^{32,33}, and antiparallel β -pleated sheets^{33,34}. The binding mechanisms could include chelation³⁵ or release¹⁷ of ions bound to the DNA and the dehydration of sterically specific carbonyl oxygens³⁶ in the minor groove on coordination with (cationic) groups of the repressor. The combined evidence^{7,28,37} is that binding is to the fully-paired DNA helical duplex, centrosymmetric with respect to the operator sequence, yet involving asymmetric contacts with bases in both strands.

Our results are consistent with the above concepts and also relevant to the question of the number of subunits involved. Several studies have established that (at least) two subunits of tetrameric repressor are required for the extremely specific and stable binding to operator^{6,7,38-40}. The interaction of repressor with natural or synthetic non-operator DNA is characterised by a much lower affinity (*K* = 10⁻⁴-10⁻⁵ M)^{25,40} and an apparent binding length *n* of 11-16^{27,28,42}. These values are similar to those reported here for headpiece (although we emphasise their tentative nature and can only set an upper limit for *n* of about 12). The probable correlation between the structure of the headpiece region integrated into the intact repressor protomer and that in the free state after proteolytic cleavage has already been discussed and is further supported by the available data for mutationally-altered

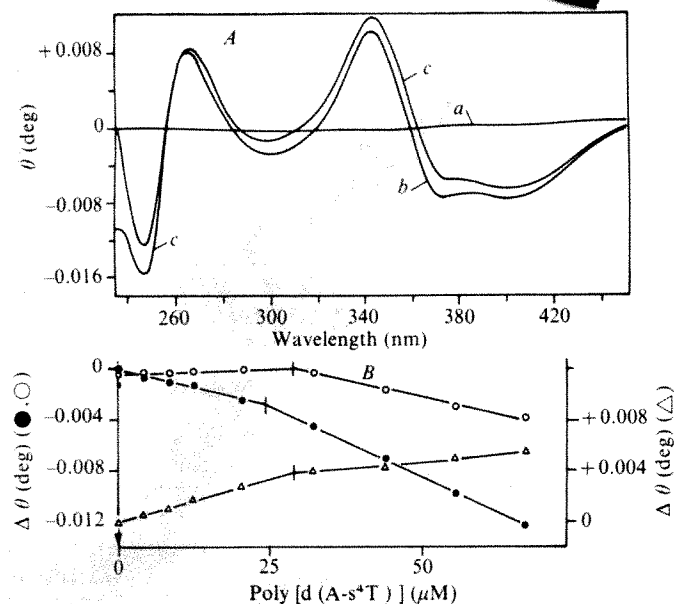

Fig. 3 Circular dichroism spectra of poly d(A-s⁴T) in the absence and presence of headpiece. *A*, CD spectrum of *a*, buffer, as in Fig. 2, at 19.3 °C; *b*, 40 μ M poly d(A-s⁴T); *c*, same solution as in (*b*) plus 26 μ M headpiece. The spectra were measured in selected 1-cm path length absorption cuvettes using the 0.04° range of a Cary 60 equipped with CD attachment. *B*, Titration of headpiece with poly d(A-s⁴T). A 2.3 μ M solution of mixed headpiece in a 1-cm cuvette was placed in the CD spectrometer and measured at 10 discrete wavelengths (only three are shown \circ , 300 nm; Δ , 357 nm; \bullet , 370 nm). Additions of poly d(A-s⁴T) were made and the cuvette mixed using a pipette but without repositioning. Two linear regions were obtained in the curves at the various wavelengths with intersections denoted by vertical ticks. The data were analysed according to the formalism for ligand lattice interactions of McGhee and von Hippel²⁵. We assume initially the case of a non-co-operative ligand (the protein) for which the binding isotherm is given by the master equation (our nomenclature) $r = L \cdot f(r)/K$ where r is the ratio of bound protein to total lattice sites S_0 (in this case taken as DNA basepairs). K is the intrinsic dissociation constant for an isolated site, L is the free ligand (protein) concentration, and $f(r) = (1 - nr)^n / [1 - (n-1)r]^{n-1}$, a function which takes into account the statistical exclusion of several potential binding sites by the attachment of a single protein molecule covering n consecutive lattice residues. In the initial region of the titration here, the ligand is in excess and the slope is given by $\alpha[1 - (1-\beta)nr]$ where α is the increment in CD signal per unit concentration of free DNA and β is the signal due to complexed DNA relative to that of free DNA residues. From the master equation, r is constant and may approach the value $1/n$ if L/K is large enough (a useful approximation for $r > n/(1+n)$ is given by $r \approx (1/n)[1 - (1/n)(K/L)^{1/n}]$). In the second linear region, the lattice is in excess and the slope is equal to α (the observed values are compatible with the spectral changes in (*A*)) and the finite x intercept is given by $\alpha n(1-\beta)L_0$ if the protein is completely bound. It follows that the intersection points defined by the extrapolations of the linear regions obey the relationship $S_0 = L_0/r$. If we assume from Fig. 1 that the LH but not the SH species was quantitatively bound ($L_0(\text{LH}) = L_0/2, r = 1/n$), then from these data $n \approx 10-14$. If these conditions were not fulfilled, n would be lower.

molecules (Table 1). The results open the possibility that the nonspecific DNA binding of native repressor in certain circumstances may involve only a single subunit of the tetramer.

We now re-examine the apparent co-operativity in headpiece binding to DNA as seen in the filter assay (Fig. 1*b*). This phenomenon could arise from (1) a concentration-dependent aggregation of headpiece to form a species with higher affinity for the filter and/or DNA; (2) a requirement for several bound protein molecules per DNA chain for successful fixation to the filter, either because of weak interactions with the latter or rapid dissociation of the binary or tertiary complexes; and (3) true thermodynamic co-operativity, that is, strong positive interaction between adjacent bound protein molecules. The chromatographic characterisation of isolated headpiece provides no evidence for (1)⁴⁰. Some possibilities under (2) are excluded by the stability of the filter-bound complex to moderate washing and the absence of a strong

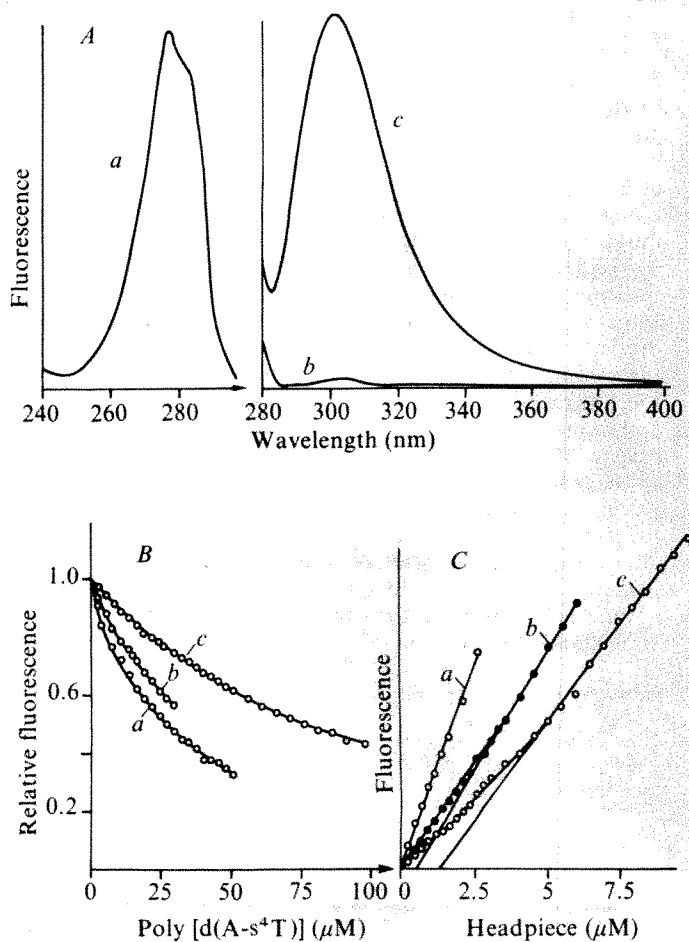

Fig. 4 Fluorescence spectra of headpiece and titration with poly d(A-s⁴T). *A*, Excitation (*a*) and emission (*c*) spectra of 2 μ M LH at 19.5 °C in the buffer given in Fig. 2. A Perkin Elmer MPF4 fluorimeter and 5-mm pathlength cuvettes were used. The spectra were recorded with a 4 nm bandwidth and are uncorrected. The excitation and emission maxima are at 275 and 303 nm, respectively. Curve (*b*) is the buffer blank emission. The spectra are virtually identical with those of tyrosine in the same conditions (the quantum yield of the headpiece, however, has not been measured). *B*, Titration of LH solutions of different concentrations with poly d(A-s⁴T). *a*, 2 μ M LH; *b*, 4 μ M LH; *c*, 13 μ M LH. Excitation was at 275 nm and emission was measured at 303 nm. The emission values after stepwise additions of DNA were corrected for dilution and for inner filter effects due to the DNA absorption (the correction factors were obtained in parallel titrations of tyrosine solutions) and normalised to the corresponding initial intensity. Pronounced curvature is evident and at the highest protein concentration the apparent values of r are improbably high (> 0.23 , corresponding to $n < 4$). In similar experiments with shorter pathlengths and using mixed headpiece preparations (4–7 μ M), the fluorescence quenching was $50 \pm 10\%$ and the apparent stoichiometry 10 ± 2 from the initial slopes. *C*, Titration of poly d(A-s⁴T) solutions of different concentration with LH. *a*, No DNA; *b*, 30 μ M poly d(A-s⁴T); *c*, 48 μ M poly d(A-s⁴T). The titrations were performed in 7-mm path length cuvettes mounted in a temperature-jump kinetic fluorimeter²⁹ using phase-sensitive detection. Excitation was at 280 nm and the emission above 305 nm was collected. Several additions of concentrated headpiece were made from a microsyringe and mixed with a magnetic bar. In contradistinction to the experiments in (*B*), the initial phases in these titrations are characterised by excess lattice (DNA) and thus protein-protein interactions are minimised. Ultimately, headpiece is in excess and the final linear slopes result from the addition of free protein (they are not identical in the three curves due to the different, but constant, inner filter effects caused by the DNA). The ratio γ of the initial to the final linear slopes of each curve obeys the relationship $1/(1-\gamma) = (K/S_0 + 1)/(1-\beta)$ from which K (the dissociation constant for an isolated complex) has a value $> 10 \mu$ M and β (the relative fluorescence of the complex) ≈ 0.5 . The x intercepts of curves (*b*) and (*c*) are given by $S_0(1-\beta)/n$, assuming saturation of the DNA, from which $n \approx 12$. The true value may be lower, however, since saturation will not have been achieved unless co-operative binding at the higher protein concentration occurs and is characterised by a much lower value of K .

chain length dependence. Certain indications for co-operativity (3) exist and are discussed in the figure legends. It has not been possible to check for sigmoidicity in solution studies by measuring a property of the DNA during addition of protein. The signals are simply too small (Figs 2, 3). Yet the behaviour at low concentration of the headpiece derived from the BG2 mutant repressor (Table 1) is most easily understood in terms of reduced co-operativity and thus a more uniform distribution of bound molecules. Retention by the filter may also require 'clusters' of headpiece or a given threshold level of complex formation. It is possible that the low values of n seen at high protein/DNA ratios (Fig. 4B) result from overlapping between binding sites, that is, occupancy by more than one headpiece molecule of the same stretch of duplex DNA. Electron microscopic evidence has been obtained recently for such a phenomenon in the case of native repressor bound nonspecifically to DNA at low ionic strength^{4,5}.

The system described here is ideal for probing general features of protein-nucleic acid interaction due to its inherent properties and the potential for extensive biochemical⁷ and genetic^{5,9} manipulations. Further physical studies using dynamic luminescence and high resolution NMR techniques are in progress.

We thank Dr B. Müller-Hill for supplying some of the bacterial strains, and Maria van der Ploeg for technical assistance.

letters to nature

Electron scattering in X ray-emitting galaxies

SEVERAL galactic nuclei have been identified as luminous sources of X rays. These include the radio galaxy Cen A (refs 1 and 2), several type I Seyfert galaxies^{1,3-5} such as NGC 4151, 3C120 and 3C390.3. The quasar 3C273 has also been detected^{1,3}. Most of these sources have been observed to vary and have, therefore, been considered compact. Their X-ray spectra, where measured, seem to indicate significant low energy absorption intrinsic to that galaxy. Examples are Cen A (ref. 2) for which the line of sight hydrogen column density (assuming solar abundances) $N_H \sim 10^{23} \text{ cm}^{-2}$ and NGC4151 (ref. 6) where $N_H \sim 5 \times 10^{22} \text{ cm}^{-2}$.

The optical depth to electron scattering, τ_{es} , is unity when $N_H \sim 1.5 \times 10^{24} \text{ cm}^{-2}$. Consequently τ_{es} is ~ 10 and 5% for Cen A and NGC4151 respectively. Higher values of τ_{es} may apply if the heavy elements are underabundant, or if a significant fraction of them is completely ionised. A scattered flux of X rays is thus to be expected from such galaxies. This flux may be detected in the time variations of the compact source if the bulk of the scattering material lies in the nucleus. A fraction $\sim \tau_{es}$ of the variations are broadened by the light travel time across the scattering region. It is likely, however, that much of the gas lies in the body, or disk, of that galaxy. In this case the scattered flux may be spatially resolvable, appearing as a diffuse extended source surrounding the nucleus. The total intensity of this extended source, I_s , is $\sim \tau_{es}$ times the mean intensity of the compact source, I_c (provided that $\tau_{es} \lesssim 1$). τ_{es} is the electron scattering optical depth weighted as to

luminosity and averaged over all directions. Note that it need not be equal to τ_{es} deduced from X-ray absorption measurements.

The spatial structure of the scattered flux depends on the underlying gas distribution and the past activity of the compact source over a time equal to that taken by light to cross that region ($\lesssim 10^4$ yr). The variability of the compact source implies that its observed intensity, I_c , need not equal \bar{I}_c , and thus I_s need not equal $\tau_{es} I_c$. I_s will, of course, exceed $\tau_{es} I_c$ in approximately half of any sample of galaxies. It is in principle possible that the past X-ray history of the nucleus can be determined by comparing independent measurements of the gas density (for example, 21 cm if the gas is predominantly neutral) with the spatial structure of the extended source.

The spectrum of the scattered X rays should be similar to that of the compact source above ~ 8 keV, but a low energy cut off due to photoelectric absorption at energy E_a should occur at $E_a \approx 8 \tau_{es} \text{ keV}$. This cutoff is related to the observed cutoff, E_{ao} , by

$$E_a \approx \left(\frac{\tau_{es}}{\tau_{es}} \right)^{1/3} E_{ao}$$

This may allow τ_{es} to be determined. Grazing-incidence telescopes such as are to be carried on HEAO-B are ineffective above ~ 4 keV, and may only detect the innermost scattered flux. Modulation collimators (such as on HEAO-A), or the lunar occultation technique (for example, EXOSAT), may prove more useful in mapping the complete scattering region. Photoelectric absorption by iron results in an absorption edge

and fluorescence emission line in the observed spectrum. The equivalent width of this line (in the scattered spectrum) is ~ 900 eV, assuming solar abundances. The scattered X rays should be highly polarised, the degree of polarisation being maximum ($\sim 100\%$) perpendicular to an edge on disk.

Both Cen A and NGC4151 are good candidates for the detection of scattered X rays. The scattered flux may already have been detected in the case of Cen A, for Delvaile⁷ reports the detection of a 3 arc min diameter X-ray source coincident with the compact source. Cen A bears some resemblance to an edge-on spiral⁸, and might therefore be a candidate for polarisation studies. The disk of NGC4151 is observed nearly face on^{9,10}, with a mean neutral hydrogen surface density over the optical spiral structure (8 arc min diameter) of $\sim 7 \times 10^{-4}$ g cm⁻² (ref. 8). τ_{es} perpendicular to the plane of the disk is thus $\sim 5 \times 10^{-4}$, which is $\sim \tau_{\text{es}}$ for the case of a thin disk containing a central source radiating isotropically. This indicates a very weak scattered flux, I_s , from most of the disk, if $I_c \sim \bar{I}_c$. τ_{es} and thus I_s may be considerably greater within the central few kpc, especially if much of the reported low energy absorption⁶ of the presumed compact source occurs in this region. Note that this compact central X-ray source may maintain a considerable fraction of the lightest elements in the inner parts of NGC4151 in an ionised state. The electron scattered flux in the infrared, optical and ultraviolet wavebands should be reddened in a similar manner to the direct flux that is detected from the galactic centre. This assumes that NGC4151 contains a distribution of dust similar to that in our Galaxy. The continuous optical spectrum of the bar in NGC4151 does, however, more closely resemble that of its nucleus than that expected from blue stars¹⁰. Optical polarisation studies could rule out electron scattering, which would imply a high degree of polarisation perpendicular to the bar.

Finally, it is worth noting that the extended X-ray source at the galactic centre¹¹ may in part be due to scattering of the X rays from the strong sources in that region.

I thank J. E. Pringle and M. J. Rees for helpful discussions.

Absorption lines in the optical spectrum of quasar AO0827+24

In January 1977 the radio source AO0827+24 (ref. 1) was observed at 90 GHz by F. Owen, S. Mufson, R. Porcas and T. Moffett with the NRAO 36-foot antenna at Kitt Peak, during observations of several flat spectrum sources selected from the Green Bank 5-GHz survey². Among these sources, 34, including AO0827+24, were found to have flux densities greater than 1 Jy at 90 GHz. Spectrographic observations of the optical counterparts of these 34 sources are in progress. We report here observations of the Mg(II) and Fe(II) absorption line system, at a redshift $z = 0.525$, in the optical spectrum of the 17.5-mag stellar object associated with AO0827+24 because of the similarity with the absorption line system of the two BL Lacertae objects PKS0735+178 (ref. 3) and AO0235+164 (ref. 4) which also have flat radio spectra.

We obtained trailed image tube spectra of AO0827+24 with a moonlight eliminator, using the 2.1-m and 2.7-m telescopes at McDonald Observatory in February and March 1977. We first took two spectra at 230 Å mm^{-1} covering the wavelength range 3,500–6,200 Å. These spectra showed a low contrast feature in emission near 3,700 Å. We later realised that a line at this wavelength had been seen in previous observations of AO0827+24 (refs 5 and 6). Wills and Wills⁶ propose an emission line redshift of 2.046 based on the line at 3,700 Å being identified with La and another emission line which they observe at 4,063 Å being identified with O(II)λ1335; they also note that against this interpretation is the apparent absence of C(IV)λ1549 and that the emission line redshift of this object is still in doubt.

The most conspicuous feature on our low-dispersion spectra was an absorption line at 4,270 Å. We therefore obtained spectra with a higher dispersion, 103 Å mm^{-1} , in the range 3,500–5,400 Å. On the best spectrum the feature at 4,270 Å is clearly resolved into two components at 4,262.5 and 4,273.5 Å and another absorption line is observed at 3,966.8 Å.

The identification of the doublet with Mg(II) 2,795.53, 2,802.70 Å gives a redshift of 0.5247. Using this value the line at 3,966 Å corresponds to a rest wavelength of 2,601.7 Å and is identified with Fe(II) 2,599.40. This line may be contaminated by the interstellar line Ca(II) 3,968 but is probably not caused solely by it otherwise we would expect to see Ca(II) 3,933 with a comparable strength, and this is not observed on our spectra.

Since the Mg(II) doublet is resolved, the full line width in the rest frame of the object is less than 7 Å or 750 km s^{-1} . The real width of the redshifted lines is not known and may be much smaller than the resolution of our spectra, which is about 8 Å. Clearly the absorption line spectrum of AO0827+24 deserves further observation, however, the available data suggest that the absorption spectrum of AO0827+24 has marked similarities with that of PKS0735+17 and AO0235+16. Since there is at least one emission line in the spectrum of 0827+24, the object is not a true BL Lacertae object. But recent results indicate that the spectrographic differences between BL Lacertae objects and quasars are not as clear cut as previously thought⁷.

In PKS0735+17 (ref. 3) only the Mg(II) doublet has been so far detected and gives a redshift $z = 0.424$. In AO0235+16 (ref. 4), there are two redshift systems, one at $z = 0.851$ determined from the Mg(II) doublet, the other one at $z = 0.524$ (which is strikingly close to the redshift of AO0827+24) determined from the Mg(II) doublet and lines of Mg(I), Fe(II) and Mn.

Interestingly, the four absorption-line redshifts in the optical spectra of these objects are all between 0.4 and 0.85. This situation may be caused in part by selection effects inherent to the spectrographic observations: the range of redshift 0.4 to 0.85, corresponds to the easily recognisable Mg(II) doublet falling between 3,900 and 5,200 Å where the search for absorption lines is the easiest.

The sample mentioned above, comprising 34 sources stronger than 1 Jy at 90 GHz, includes AO0827+24 and also the two BL Lacertae objects PK20735+17 and AO0235+16. Thus at least three out of 34, or about 10% of the objects, show similar absorption line systems with $z < 0.9$; the incidence of such absorption systems is therefore not uncommon. It is not known at present whether this phenomenon is caused by cold gas clouds ejected by the continuum emitting source or by intervening galaxies. If these absorption lines are caused by intervening galaxies, they should be present in the same percentage of the spectra of all QSOs with $z > 0.9$ regardless of their optical and radio properties. The incidence of absorption lines in the spectra of QSOs with emission lines of width and strength similar to those found in BL Lacertae objects is not known since up to now QSOs have generally been observed with a low dispersion sufficient to detect broad emission lines but inadequate to resolve and thus recognise the Mg(II) doublet; this is in contrast to the spectra of the BL Lacertae objects, especially the bright ones, which are thoroughly searched for

absorption lines. Clearly a systematic search for absorption lines in the spectra of QSOs will be useful for determining their origin.

NRAO is operated by Associated Universities, Inc., under contract with the NSF.

Prebiotic polymers and infrared spectra of galactic sources

INFRARED absorption features characteristic of molecular dust clouds in the Galaxy may be assigned to complex organic polymers or prebiotic polymers. It could be argued that such highly stable, complex polymers evolve due to radiation processing of molecular mantles on interstellar grains—essentially by a type of natural selection which operates in the interstellar medium. A large fraction of all C, N, O elements in the interstellar medium could be condensed in the form of these stable polymers. Such interstellar material may also account for a significant fraction of the 'insoluble organic matter' which is found in carbonaceous chondrites.

The chemical composition of interstellar dust is uncertain. Observations of infrared excesses in cool stars combined with appropriate thermodynamic calculations support the view that grains comprised of silicates, iron and graphite are produced in these stars¹. It is unlikely, however, that these materials alone can satisfactorily explain the entire range of optical data relating to interstellar grains². Measurements of interstellar linear and circular polarisation point strongly to the dominance of a dielectric grain material at optical wavelengths³. Furthermore, estimates of the mean extinction coefficient of interstellar matter together with cosmic abundance data imply that the large bulk of grain material is comprised of C, N, O elements². These elements, in appropriate combinations with hydrogen, may exist as molecular mantles on grains. Mixtures of inorganic ices were proposed by van de Hulst⁴,

Fig. 2 Absorbance (A) of organic polymers as a function of wavelength. *a*, Polyformaldehyde (Delrin acetal resin); *b*, polyvinyl alcohol; *c*, natural resin: Shellac—regular bone dry, bleached—FEXO type¹². *d*, Average absorbance for 18 selected polymers of various types.

and N.C.W.⁵ has discussed the possibility of formaldehyde polymers. These two types of composition could represent intermediate stages in a progression towards an increasingly complex macromolecular structure for grain mantles.

We envisage the evolution of grain mantles in two distinct steps. First a mixture of relatively simple organic and inorganic ices (for example, CO, H₂O, NH₃, H₂CO) condenses on silicate grains in interstellar clouds. The combined effect of interstellar cosmic rays, X rays and ultraviolet photons on these grains will be to initiate solid-state polymerisation reactions of the type discussed by Goldanskii⁶. The end product of such processing of grain mantles is a stable, radiation-resistant organic polymer or prebiotic polymer. Such polymers may be thought of as evolving according to a type of natural selection in response to a wide range of selective pressures operative in the interstellar medium. It is possible that the low abundances of simple molecules and radicals (for example, OH, CH, CN) observed in diffuse interstellar clouds is maintained by a very slow degradation of these polymers.

Infrared absorption features observed in galactic sources, include bands centred on 3.1, 3.4 and 8–12 and ~20 μm. The most extensive observational data are available for the 8–12 μm feature. This band is seen in emission by hot dust in HII regions and circumstellar shells, as well as in absorption against sources of continuum infrared radiation. A silicate explanation for the 10 μm band seems natural for many sources exhibiting this feature, particularly in cases where dust is observed in circumstellar shells around oxygen-rich M giant stars⁷. Similarly, an H₂O–ice explanation for the 3.1-μm band may be tenable in some cases. In sources of exceptionally strong absorption, for example, the BN object in the Orion nebula, there are inadequacies in this conventional point of view.

Figure 1 shows the infrared spectrum of the BN object, which is probably one of the most heavily reddened objects in the Galaxy⁸. Here we see absorption bands centred on wavelengths close to 3

Fig. 1 Infrared spectrum on the BN object in the Orion Nebula⁸.

and 10 μm . The 10- μm band is usually attributed to silicates, and the 3- μm bands to H_2O -ice. Both these compositional assignments present problems. If we assume that the overall composition of dust which obscures the BN object is representative of grains in the general interstellar medium, the mass ratio of ice to silicates which is consistent with the observed relative strengths of the two bands in Fig. 1 is inconsistent with cosmic abundance criteria^{2,9}. Also, the detailed shape and width of this 10 μm band does not give a satisfactory fit with the absorption spectrum of any known silicate.

Table 1 Vibrational frequencies for various linkages in organic molecules¹¹

Bond	Wavelengths (μm)
C-C, C-O, C-N	7.7-12.5
C=C, C=O, C=N, N=O	5.3-6.7
C \equiv C, C \equiv N	4.4-5.0
C-H, O-H, N-H	2.6-3.7

Another case which presents difficulties for simple silicate-ice models is the infrared spectrum of a source at the galactic centre. A broad 3- μm band, which includes a weak feature at 3.4 μm , cannot be explained in terms of a simple model of H_2O -ice grains¹⁰. Likewise, the deep, narrow absorption band centred on 9.7 μm in this source⁷ cannot readily be explained by silicate-type grains.

The possibility that organic polymers could contribute to absorptions at 3, 3.4 μm , and over the 8-12- and 18-24- μm wavebands in galactic sources suggests that organic polymers could provide a potentially more flexible and viable explanation of astronomical absorption spectra at near and mid-infrared wavelengths compared with silicate grains. The mass density of absorbing material in this former category may be higher by an order of magnitude, because of the higher cosmic abundance of C, N, O elements.

Organic molecules and polymers are known to have broad absorption bands in the wavelength region 1-100 μm due to transitions between vibrational-rotational levels. Over the waveband 2.5-13 μm considered above, stretching modes of elementary bonds which contribute to absorptions are listed in Table 1.

The precise positions of band centres and band widths appropriate to individual groups depend on associated linkages and on the particular molecular environment in which these groups are placed. From extensive spectral data¹² on organic polymers, absorption features in the wavelength ranges 8-12 and 2.5-3.5 μm are seen to be the most persistent properties encompassing natural and synthetic polymeric compounds of widely ranging types.

Figure 2 shows the absorbance spectra of an acetal resin (a), polyvinyl alcohol (b) and a natural resin (c). While we could not find a single spectrum of a simple polymer which provides a satisfactory fit to the data in Fig. 1, the average spectrum of a number of different types of polymer tends to produce a relatively structureless, broad 10- μm band giving better agreement with this astronomical absorption feature. Figure 2d represents a synthetic spectrum obtained simply by averaging absorbance data^{11,12} for a selection of 18 polymeric species. The selection was made so as to include polymers of a wide variety of types, but with a bias towards those which exhibited broad bands centred near 3 μm due to either O-H or N-H stretching modes. This 'synthetic' curve is fairly close to a smoothed out mean of the three absorbance spectra Fig. 2a, b and c. Although we cannot claim any uniqueness for our synthetic spectrum (d), this curve provides significantly better agreement with the BN source data (Fig. 1) than any model involving silicate-ice grains. This cannot be dismissed as fortuitous. A smooth absorption feature of appreciable strength in the 8-12 μm waveband arises quite naturally for an average polymer spectrum, if we take a large enough number of polymers of various types^{11,12}. But the requirement of either a strong 3- μm band or a 3.4- μm band demands a more restrictive choice. In this context it is worth noting that some galactic sources show strong bands at 3.4 μm , but not the usual 8-12- μm feature. A case in point is the emission spectrum of the planetary nebula NGC7027 (ref. 13). It is also interesting that some astronomical data, including the extended infrared emission source in the Trapezium nebula¹⁴, indicate a significant absorption coefficient in the '10- μm band' of interstellar dust extending to $\lambda \geq 13 \mu\text{m}$. There are other cases where a 3- μm absorption band, wider than one which can usually be attributed to ices, occurs together with a broad 8-13- μm band¹⁵. Such absorptions cannot readily be explained by silicates and H_2O -ice but could be obtained by biasing our organic compound mix to include a substantial fraction of amides. These compounds have a broad 3- μm feature due to N-H stretching as well as a broad absorption feature in the 12.5-15- μm region due to out-of-plane NH wagging¹¹; a typical case is the spectrum of isobutyramide¹¹.

Fig. 3 Infrared absorption spectrum of sporopollenin from *Tasmanites punctatus* fossil planktonic algae. Sporopollenin is an oxidative co-polymer of carotenoid-carotenoid esters containing the molecular and macromolecular groupings shown above.

An exceedingly complex organic or prebiotic polymer which evolves in the interstellar medium could well possess absorption properties similar to those of the synthetic polymer spectrum Fig. 2d. Alternatively, the average interstellar absorption curve may be due to an ensemble of less complex polymers which has an average spectrum similar to Fig. 2d. In the context of the former possibility, it may be of interest to consider the properties of highly stable naturally occurring biopolymers.

A particularly stable polymer of this type is sporopollenin, an oxidative copolymer of carotenoid-carotenoid esters, which forms a major component of pollen and many spore walls. Figure 3 shows the infrared absorption spectrum of sporopollenin from *Tasmanites* fossil planktonic algae over the wavelength region 2.5 to 40 μm . This spectrum shows a broad absorption feature at 3 μm , a narrower 3.4- μm band, and a deep and somewhat narrow absorption band at 9.7 μm generally similar to data for the galactic centre infrared source^{7,10}. In Fig. 3 there is also a band at 20 μm similar to one which is regarded as providing additional evidence for interstellar silicates. Sources where the detection of a 20- μm band has been claimed include the Trapezium and KL nebulae¹⁶.

Although these spectral similarities do not prove the presence of sporopollenin in interstellar space, nor indeed of any biopolymer, there is an indication here of a fairly complex, radiation-resistant prebiological polymer associated with interstellar grains. It is possible that the conversion of interstellar grain mantles into radiation resistant polymers, and the formation of protective coatings on pollens and spores followed similar chemical pathways, in response to broadly similar selective pressures. Prebiotic polymers with large-scale molecular groupings similar to those occurring in sporopollenin (but less complex) may be the net result of such an evolution. Infrared spectra of these two systems could be fairly similar.

We have already suggested an identification of the λ 2,200 Å interstellar absorption band with electronic transitions in conjugated multiple bonds of prebiotic molecules¹⁷—such molecules being supposedly trapped within polymeric matrices of the type considered here. Sakata *et al.*¹⁸ have also shown that a similar ultraviolet absorption feature occurs in the soluble organic matter extracted from a carbonaceous chondrite. This similarity in ultraviolet spectra was interpreted as support for the inclusion of primitive grain clump material in meteorites. In view of the infrared spectral identification suggested here, we might further argue that the insoluble organic matter of carbonaceous chondrites may also have an interstellar origin. This material is too complex for detailed identification, but is believed to be comprised of highly condensed aromatic polymers which account for nearly 70% of the total carbon content in these meteorites¹⁹. Such prebiological polymers, processed in the interstellar medium, could have played a crucial part in the evolution of terrestrial life.

We (F.H. and N.C.W.)²⁰ have also shown a strong case for the class of biopolymer—polysaccharides—in interstellar dust. Other organic polymers such as discussed above would probably be less abundant than polysaccharides.

Atmospheric absorption between 4 and 30 cm^{-1} measured above Mauna Kea

CONSIDERABLE attention is being given to the construction of new telescopes which will extend ground-based astronomical observations to millimetre and sub-millimetre wavelengths, and so it is essential to have a better understanding of atmospheric absorption at these wavelengths. We report here measurements made from the summit of Mauna Kea in Hawaii of the absorption of radiation coming through the atmosphere in slant paths from the sun. These have extended previous knowledge of absorption at this site^{1,2} to lower frequencies and have confirmed that a little understood phenomenon which we call anomalous absorption can greatly reduce atmospheric transparency at some millimetre wavelengths theoretically predicted to be good windows. To compare our measurements with theoretical predictions, particular attention was paid to determinations of atmospheric water content in the same path from the sun. A complete absorption band near 1.4 μm was scanned, therefore, using a monochromator and values of precipitable water were derived by well known formulae³.

Spectra in the wavenumber range 4–30 cm^{-1} were obtained by Fourier inversion of the output of a Michelson interferometer which was illuminated by a 50-cm diameter telescope and used a Golay detector. Interferograms giving a resolution of 0.5 cm^{-1} were recorded in 30 min. As the sun is nearly a black body at these frequencies, a local black-body source was used

Fig. 1 Measurements in January–February 1976 at Mauna Kea (elevation 4.2 km, latitude 19°50', longitude 155°28'). The solid line is an average transmission spectrum for which the mean zenith angle is 55°. The resolution is 0.5 cm^{-1} . Below 20 cm^{-1} the average is from nine days of observation with a mean water vapour content of 1.9 mm precipitable in the path. Above 20 cm^{-1} the average is from the four driest days, with 0.9 mm precipitable. The displaced error bars represent the standard deviation of the noise on the spectra. The dotted line shows theoretical predictions in which the small oscillations between known lines come from including the effects of the instrumental 'spectral windows'. Arrows mark O_2 lines, other lines are due to water.

Fig. 2 Daily averages of transmission at 7.7 cm^{-1} plotted against the measured water vapour content. Mean zenith angles are in the range $47\text{--}61^\circ$. The dashed line shows predicted transmission.

to provide a calibration by which day-to-day changes in radiometric sensitivity could be followed and also give a reference spectrum by which the solar spectra were divided to measure atmospheric transmission. As we could not record a solar signal without absorption, measurements for one day of particularly high atmospheric transparency were used to establish the transmission scale. We selected a wavenumber of 10.3 cm^{-1} where there is low atmospheric absorption and assumed that the only loss was that predicted by the theoretical model corresponding to the measured water content. We found that on that day the signal strength varied with zenith angle by the expected amount. Figure 1 shows a composite spectrum from several observations averaged as described in the legend. These data were obtained in clear conditions and for the wavelengths under discussion this means that attenuation by particles could be neglected. Theoretical spectra were calculated from AFRL tabulations of molecular line parameters⁴.

As well as the expected lines of water and oxygen, additional absorption was observed which seriously affects 'windows' used for astronomical observation. The extra component is described as anomalous absorption and no simple correlation between its strength and atmospheric water content was found. Figure 2 shows this in the behaviour of the atmospheric window near the astronomically important $J = 1 \rightarrow 2$ pure rotation line of carbon monoxide at 7.7 cm^{-1} . At this frequency the average absorption was 2.1 dB where the water vapour and oxygen model predicts 0.23 dB for the mean water content of 1.9 mm precipitable.

As an alternative to radiometric calibration, it is common practice to assess atmospheric absorption by measuring signals as a function of the zenith angle from an astronomical source. Assuming that the absorbers are horizontally stratified and do not vary in concentration during a sequence of measurements, a plot of absorption against airmass would be a straight line through the origin. Plotting absorption values for the interval 7 cm^{-1} to 9.5 cm^{-1} measured in this way, we found that the intercept at zero airmass was significantly greater than zero on most days, as shown in Fig. 3. This suggests that stratification of the molecules giving rise to anomalous absorption may be affected by the presence of the mountain and that the method of calibration based on zenith angle dependence, though widely used, may not apply in such circumstances.

We conclude that anomalous absorption, frequently reported⁵ in qualitative terms, is a major phenomenon at Mauna

Kea. The observed magnitudes are similar to values previously obtained at Mauna Kea¹, and other mountain sites^{6,7}. The variability in the effect which we observed is sufficiently great that these observations are not necessarily in conflict with the low values recorded at White Mountain, California⁸. The amount of anomalous absorption in the range $7\text{--}9.5 \text{ cm}^{-1}$ is consistent with what has been found in horizontal atmospheric paths⁹ if reasonable values of scale height for absorbers are assumed. The non-zero intercept on the absorption against

Fig. 3 Each point, which represents absorption averaged over the 7.0 cm^{-1} to 9.5 cm^{-1} interval, was measured in the same day. The error bars give an estimate of the standard deviation of the noise in this interval. Airmass is defined as the ratio of the amount of atmosphere along the observing path to the amount in the zenith direction. The line fitted to the data gives an intercept of $1.7 \pm 0.2 \text{ dB}$.

airmass plot suggests that there may be factors specific to a site which can enhance anomalous absorption.

We thank Professor J. T. Jefferies for the use of Mauna Kea Observatory, University of Hawaii, also Mr T. Krieger and his staff at the Observatory for their assistance.

Carbonate mineral detection by variable atmosphere differential thermal analysis

GREATLY improved detection limits for the presence of anhydrous carbonate minerals in mixtures with other types of minerals can be obtained by variable atmosphere differential thermal analysis (DTA) using dynamic furnace atmospheres of CO_2 (flow rate 100 ml min^{-1})¹. Details will be published elsewhere^{2,3} (see ref. 1 for details of the Du Pont unit and conditions of analysis). These carbonates fall into two groups: those which decompose in CO_2 with single, or multiple⁴ endothermic dissociation reactions liberating CO_2 . The first group contains, calcite CaCO_3 , magnesite MgCO_3 , smithsonite ZnCO_3 , and siderite FeCO_3 (ref. 5); while the second includes dolomite $\text{CaMg}(\text{CO}_3)_2$, ankerite $\text{Ca}(\text{MgFe})(\text{CO}_3)_2$ and cerussite PbCO_3 (ref. 4). Here calcite and dolomite are taken as typical examples and their behaviour described.

In conditions of dynamic CO_2 compared with static air, the single endothermic peaks of group one members show several important DTA curve modifications (Fig. 1*b* and *c*): peaks become narrower, and more sharply defined with much increased peak heights: the complete peaks, including initial, peak and final temperatures, move up scale to occur at considerably higher temperatures.

The multiple endothermic peaked second group behave differently in the same conditions (Fig. 1*d* and *f*): the initial peak becomes displaced down scale^{2,6} (sometimes, due to crystallinity and equipment, for low concentrations, the known fall in peak temperatures due to dilution when determined in air⁶ and their relative stability in dynamic CO_2 may cause both dolomite peaks to appear up scale from the fused composite peak representing them in air (Fig. 1*d* and *f*)). The higher temperature peak (dolomite) or peaks (ankerite) move up scale to occur at higher temperatures with considerably increased and decreased peak heights and widths respectively: markedly increased peak sep-

aration and definition results. Individual peaks remain recognisable down to the limits of detection (see Fig. 1*e*) and do not, with progressive content dilution coalesce into the single broad similar (difficult to identify) features which typically result from determinations in air (compare Fig. 1*d* and *f*). The size of the now clearly resolved middle endothermic peak of ankerite, varies with iron content².

The DTA of such carbonates in these conditions enables their greatly improved detection down to contents in the order of 0.25% ³, the identification of members of the dolomite-ferroan dolomite-ankerite series² and the detection of 'iron carbonate' components, present either as siderite or ankerite-ferroan dolomite with detection limits and content evaluations² which seem considerably superior to those obtainable by routinely available X-ray diffraction data, which emphasises the potential of DTA in this aspect of determinative mineralogy.

I thank the University of Bristol (Geology) and the Macaulay Institute for Soil Research (Pedology) for the opportunity to undertake this work during the tenure of a visiting professorship.

Δ^2 -Sterenes as diagenetic intermediates in sediments

A SMALL fraction of the sterols derived from living organisms is found intact or partially degraded in the geological environment. Seawater and many recent or relatively immature older sediments contain unaltered, or only slightly altered sterols¹⁻⁸, whereas in older sediments and petroleum these compounds have usually been transformed by redox reactions into their saturated (steranes) or partially aromatised counterparts⁹⁻¹². Due to the high stability of the steroid skeleton, products derived from steroids can be detected in consolidated sediments far into an advanced stage of maturation. We have examined 11 recent sediments and suggest here that the Δ^2 -sterenes which they contain are degradation intermediates of the precursor sterols.

The characterisation of degradation intermediates, for example, unsaturated hydrocarbons, can bring a better understanding of the nature of the evolution pathways undergone by the sterols in the sedimentary environment, as well as useful information on the stages of evolution at which various degradation reactions take place¹³. Mono- and di-unsaturated steroid alkenes have been tentatively detected in various sediments, but these compounds have not been conclusively identified¹⁴⁻¹⁶.

We have now studied the unsaturated hydrocarbon fraction of 11 recent sediments—five from the sea of Norway, one from the Baltic sea, two from the vicinity of the Amazon estuary, one from the Cariaco Trench near Venezuela and two continental muds from the immediate vicinity of Strasbourg. The samples were frozen and freeze-dried immediately after collection. The dry samples were then extracted with freshly-distilled chloroform in a Soxhlet apparatus or under ultrasonics. When necessary the total extracts were desulphurised on active copper and separated by thin-layer chromatography (TLC) on SiO_2 with hexane elution. The unsaturated hydrocarbons (10-20% of the total saturated + unsaturated hydrocarbons) were further separated by Ag^+/SiO_2 TLC with hexane elution yielding 1-2 p.p.m. by weight based on

Fig. 1 Differential thermal analysis curves of calcite and dolomite obtained from artificial mixtures of *a*, 0.5% calcite; *b*, 6% calcite; *c*, 6% calcite; *d*, 6% dolomite; *e*, 0.5% dolomite; *f*, 6% dolomite by weight with calcined alumina. Determinations being made in furnace atmosphere conditions of static air (dotted line) or dynamic carbon dioxide (solid line). The much improved peak definition, resolution and detection limits are clearly shown by the curves determined in dynamic carbon dioxide.

dry sediment (standard precautions against contamination necessary in organic geochemical studies were taken throughout). Gas chromatographic (GC) analyses were carried out on 1% Dexsil-packed glass columns (2.5 m \times 3 mm) and OV-101 and Apiezon L capillary columns (25 m \times 0.5 mm i.d.) using a GC-mass spectrometry-computer set-up (LKB 9000 S/PDP 11E 10). In control experiments a solution of 70 mg of pure cholesterol in chloroform was treated with 50 g of a chloroform pre-extracted sediment under ultrasonics: no trace of Δ^2 -sterenes could be detected after extraction and separation following the analytical procedure described above.

We have identified, from the unsaturated fractions of the recent sediments studied, three major constituents (Fig. 1) as the C_{27} , C_{28} and C_{29} $5(\alpha H)$ Δ^2 -sterenes *a-c* by the following criteria: mass spectral fragmentation patterns identical with those of the corresponding Δ^2 -sterenes which we and others¹⁷ had prepared, and co-elution with the reference compounds (C_{27} and C_{29}) on two capillary columns (OV-101 and Apiezon L). The mass spectra of the Δ^2 -sterenes show significant differences from those of Δ^4 - or Δ^5 -sterenes, since the former are characterised by an important fragment at *m/z* 54 (loss of butadiene due to a retro-Diels reaction)¹⁸. Stereochemistry at C_{24} remains undetermined.

Fig. 1 Gas chromatogram of the unsaturated hydrocarbons of a recent marine sediment (5,000 yr) from the Cariaco Trench, near Venezuela. Conditions: OV 101, 25 m \times 0.5 mm i.d., 130–270 $^{\circ}C$, 3 $^{\circ}C$ min⁻¹. Peaks correspond to the Δ^2 -sterenes: *a*, $R = H$; *b*, $R = CH_3$; *c*, $R = C_2H_5$.

Recent results are good evidence for the microbiological reduction of Δ^2 -sterols into the corresponding $5\alpha H$ (and $5\beta H$) stanols in the first stages of diagenesis in surface sediments^{7,19,20}. The Δ^2 -sterenes (which have so far only been reported in non-fat dry milk¹⁷) may be formed in a further stage by dehydration of the corresponding stanols. In one of our samples, from the sea of Norway, which showed a slightly acidic pH, we noticed the concomitant presence of a series of $\Delta^{13(17)}$ -sterenes (C_{27} – C_{29}) with a backbone-rearranged skeleton. It is reasonable to assume that these compounds, which we have previously identified in several older shales, are formed from stanols by an acid-catalysed skeletal rearrangement through Δ^2 -sterene intermediates. This process has been clearly demonstrated by simulation experiments with cholesterol or Δ^2 -cholestene and montmorillonite clay²¹. Further studies, however, are still needed to confirm that the isolation of rearranged sterenes is really due to the observed low pH.

The identification of Δ^2 -sterenes in various recent sediments deposited in marine or continental environments suggests that these compounds are degradation intermediates of the precursor sterols, via the corresponding stanols, in the sedimentary environment. It is also possible that they arise directly from stanols, since

Fig. 2 Early transformations of sterols in the geological environment, based on laboratory and field results. Processes marked ? are only inferred (see refs 8, 9, 20, 21 and refs therein) $R = H, CH_3, C_2H_5$.

the latter have been detected in several living organisms⁸. These alterations start at a very early stage of diagenesis in surface sediments. These results, combined with our, and other authors' previous results, increase our knowledge of the first geochemical evolution pathways undergone by the sterols in the geological environment, as shown in Fig. 2.

This work constitutes a contribution to the 'Projet ORGON', an interdisciplinary approach study of recent sediments undertaken by several French laboratories. We thank ELF-Aquitaine for financial support.

High shear velocity layer in the upper mantle of the Western Pacific

SHEAR waves have been only rarely observed in explosion seismology studies at sea, so their precise velocities have not been extensively studied. An inversion method from seismic surface wave studies has been used to measure the shear wave velocities of the oceanic upper mantle¹⁻³. But, the values obtained, generally 4.6 km s^{-1} , are inherently an average of a path from a seismic source to a seismic recording site on land, so that the method can not give a 'pure' value for the upper oceanic mantle. Shear wave velocity is, however, important for the physical property of the upper mantle as well as for discriminating the minerals which make up the oceanic upper mantle. We describe here our measurements of apparent shear wave velocities, using 61 natural earthquakes with epicentral distances ranging from 400 to 2,900 km. Results indicate that the lower part of the oceanic lithosphere contains a large amount of garnet.

A linear array of high sensitive ocean bottom seismographs (OBSs) was positioned on the Western Pacific Basin, where the Pacific lithosphere is thought to be very old and about to subside (Fig. 1). The water depth is between 5,500 and 5,600 m. The linear dimension of the array is about

Fig. 1 A map showing the array of ocean bottom seismographs (▲) and precisely located epicentres of earthquakes, having focal depths shallower than 40 km (○), 41–70 km (●), and 71–190 km (■). Note that most of the wave paths from the foci to the OBS array pass through the upper mantle of the Pacific lithosphere (if we consider that the lithosphere is subducting north-westerly); hence the obtained apparent velocities represent those of Pacific upper mantle. □, 7- and 5-t explosions which were used for the explosion seismology study⁴ where P-wave structure has been obtained for the region.

400 km, so that the apparent velocities were accurately measured within the array⁴.

The observations were carried out during a two-week period in October 1974, when 61 shallow earthquakes were precisely located by various land seismograph networks (Japan Meteorological Agency, USGS, the seismological network of Sakhalin Complex Scientific Institute USSR, seismological networks operated by Tokyo University and Hokkaido University in Japan). Most of the earthquakes occurred along the Kuril trench and Japan trench which are, seismically, the most active regions in the world. Since the OBSs are sensitive, earthquakes with magnitude 3 or 4 were clearly recorded at distances of 1,000 or 1,600 km, respectively.

Our observed S travel times, from earthquake foci to the OBSs, are shown in Fig. 2. These are markedly smaller than those of the Jeffreys–Bullen travel time tables. The differences are 10–30 s for shallow earthquakes with 400 to 1,800 km range of epicentral distances. The results indicate that the structure of the oceanic upper mantle at the Western Pacific is unusual. Travel times, however, have inherent limitations in resolution since they are strongly affected by errors in their origin times which are given by seismograph networks on land.

Apparent velocities, which are measured from passing times of seismic waves which cross the OBS array and indicate the velocities of the rocks at the deepest points of seismic rays, are accurate, since they are free from errors in the origin times. Although they give useful information, the apparent velocities are the least sensitive quantity to the complexity of the structure.

The region west of the trenches probably has a complicated structure that includes a continental shelf overlying a subducting lithosphere. The structure may cause errors in the determination of hypocentres and deflections of seismic waves which are incident to the OBS array.

Some calculations on ray paths, using plausible velocity models for the region, reveal that the complexity of the region's structure cannot affect the obtained apparent velocities by more than 1%. The size of the error is the result of choosing earthquakes with small errors in focal positions for our analysis and also that the earthquake foci are very close, in a three-dimensional sense, to the plausible subducting lithosphere, which is considered to subduct towards the north-westerly from the trenches.

The apparent velocities were calculated from pairs of readings by adjacent OBSs, which are indicated by line segments in Fig. 2. Figure 3 demonstrates that V_s values are faster than 4.6 km s^{-1} . The average value, $4.88 \pm 0.12 \text{ km s}^{-1}$, is obtained from 59 data for shallow earthquakes, since calculated velocities seem to have little dependency on epicentral distances within the range of the figure. The small standard deviation suggests the accuracy of overall measurements of this analysis, which are composites of errors in source locations, errors in OBS locations, timing errors in OBS and the possible inhomogeneities of structures beneath the OBSs sites. The effect of incident angle to the array has been compensated.

The obtained value of S-wave velocities, which show a predominance at 4.9 km s^{-1} , in all probability corresponds to the P-wave velocity of 8.6 km s^{-1} , which has been obtained by a long-range explosion seismology study³ and apparent velocity measurements for P waves⁴, at the same region. Hence from a probable analogy to the P-wave structure which was measured by the explosion experiment, the measured S value, 4.9 km s^{-1} for the range 500 through 1,800 km of epicentral distances, indicates the S-wave velocities in layers from 60 km to about 150 km depths, except for the low velocity layer.

The existence of the low velocity layer, which is observed by the explosion experiment and apparent velocity measure-

Fig. 2 Travel times of earthquakes, whose epicentres are shown in Fig. 1, observed by the OBS array. \circ , \bullet and \blacksquare as for Fig. 1. Each group of short line segments denotes an event of an earthquake. Travel times of Jeffreys-Bullen, for focal depths of 0, 33, and 100 km, are also shown. The observed travel times are remarkably faster. Vertical dotted lines are possible offsets.

ments for P waves, is also suggested by the present S-wave study. The effect of the low velocity layer beneath the oceanic lithosphere is demonstrated by offsets of travel times⁴. This is the case for S waves. The observed offsets are indicated in Fig. 2 by dotted lines. Although we could not obtain the V_s value in the low velocity layer since it is not observed as an apparent velocity, the thickness of the low S-velocity layer is estimated to be as thin as that of the low P-velocity layer which was measured to be less than 50 km (ref. 5), if we consider the travel time differences at the observed offsets. We conclude that the oceanic upper mantle at the Western Pacific mainly consists of 4.9 km s^{-1} layer, except for the uppermost 4.6 km s^{-1} layer with a probable small thickness and the low velocity channel which also has a small thickness. The depth of the bottom of the 4.9 km s^{-1} layer was not known accurately.

The V_s value of 4.9 km s^{-1} sets an important limitation on the candidate minerals which could make up the oceanic upper mantle. M. Kumazawa has measured V_p and V_s for the various minerals which have been considered as components of the oceanic upper mantles, under various temperatures and pressures (personal communication). A description of the pressure at the lower part of oceanic lithospheres has thus been obtained, although some ambiguities which are mainly effects of temperature and pressure, have been introduced. A three-component composite rock—the most probable composition for the oceanic lithosphere—is assumed (see Fig. 4).

Figure 4 indicates that pure olivine, pure pyroxene or a mixture of olivine and pyroxene fails to meet the seismo-

Fig. 3 Apparent velocities obtained from Fig. 2. Only shallow earthquakes with focal depths less than 40 km are used to obtain an average velocity of $4.88 \pm 0.12 \text{ km s}^{-1}$. \circ , \bullet and \blacksquare as for Fig. 1; broken circles are less reliable, data are probably contaminated by a possible inclusion of offsets in the span of the OBS array.

logically-obtained values, unless an impossible temperature, such as lower than 250°C , is assumed. Therefore, a considerable amount of garnet is necessary to explain the high velocities of P and S, despite the fact that garnet has not been widely accepted to be a major component of oceanic lithosphere (except by Ito⁶). The content of garnet in the lower part of lithosphere is also suggested by Fig. 4 to be probably more than half, possibly 60 to 80% of all the minerals present, under any assumption of temperature which has been generally accepted, that is $500\text{--}1,000^\circ\text{C}$.

Although the finer structure of the lower part of the oceanic lithosphere has not been elucidated in this study, a probable mechanism to compensate for the increase of V_p and V_s due to higher pressure towards the bottom of the

Fig. 4 Seismic wave velocities of the three-component composite rock at a pressure of the top of the high velocity layer in the oceanic lithosphere, for various conditions of temperature. The postulated components are garnet [70% pyrope ($\text{Mg}_3\text{Al}_2\text{Si}_3\text{O}_{12}$) + 30% almandine ($\text{Fe}_3\text{Al}_2\text{Si}_3\text{O}_{12}$)], pyroxene [90% enstatite (MgSiO_3) + 10% ferrosilite (FeSiO_3)] and olivine [90% forsterite (Mg_2SiO_4) + 10% fayalite (FeSiO_4)]. The measured velocities, $8.64 \pm 0.13 \text{ km s}^{-1}$ for V_p (ref. 4) and $4.88 \pm 0.12 \text{ km s}^{-1}$ for V_s , from ocean bottom seismometry are also shown.

oceanic lithosphere by the decrease of V_p and V_s due to increase of temperature has been suggested, which results in the fairly uniform values of V_p and V_s for a wide range of depths, that corresponds to a wide range of the epicentral distances (Fig. 3).

Another layer of 4.9 km s^{-1} which lies beneath the low velocity layer, may also be accounted for by the identical garnet-rich rock because of a similar compensation. But uncertainties of high temperatures and pressures effects in the range obstruct any definite interpretation.

We are planning another experiment in which OBS array will be placed perpendicular to that of the present study, which means an array perpendicular to the local magnetic anomaly: this should show whether or not V_p and V_s values larger than $8.6\text{--}4.9 \text{ km s}^{-1}$ can be obtained.

We thank Dr K. Ito for helpful discussions.

Uranium series ages and late Quaternary uplift in the New Hebrides

CURRENT interest in geodynamics has stimulated research into late Quaternary uplift rates of the Earth's crust from uranium series age determinations of elevated coral reefs^{1,2}. Of particular interest is the subduction rate of the Australian Plate beneath the New Hebridean Island Arc along the New Hebrides Trench (Fig. 1) derived using the uplift rate of a pre-subduction lithosphere flexure near the south-eastern Loyalty Islands^{3,4}. We report here seven uranium series ages of elevated coral reefs in the New Hebridean Islands in the hope that estimates of uplift rate in the island arc will provide additional constraints for Quaternary plate-tectonic models.

The history of the New Hebridean islands since their formation in the Oligocene is relatively well known⁵⁻⁷. Before the Pliocene, the rocks deposited were largely basalt and volcanoclastic sediment. In the late Pliocene substantial deposition of reef limestone became common⁸, especially in the eastern and western belts of the archipelago indicating slow sinking of most of the archipelago for 1 or 2 Myr. Since about the mid Pleistocene, however, many islands of the group rose progressively above sea level, as is indicated by flights of raised reefs along their coasts.

Raised reef sequences have been described on Malekula⁸, Pentecost⁹, Efate⁷, and Malo Island¹⁰ (Fig. 1). The general appearance and sedimentary analysis of the reef capped terraces on Malekula suggest that they were formed by transgressive-regressive cycles, probably resulting from eustatic sea-level oscillations, combined with continuous uplift of the coastal section concerned⁸. Similar models, supported by uranium series age, have been advanced for raised reefs on Barbados^{11,12}, the Ryukyu Islands¹, the Huon Peninsula of New Guinea^{13,14} and Timor and Atauro in the Banda Arc².

The ages presented here are from samples collected (by G.N.) on Efate and Malo Islands during May 1974. The raised reefs form good topographical features but they are rarely well exposed and road cuts are the best collecting sites. Heights were estimated by two pocket altimeters and these readings are consistent with contours of the 1:100,000 topographical maps published by the Institut Géographique National, Paris. Radiometric analyses have been carried out (by H.H.V.) using methods previously described². The results are shown in Table 1.

Although only a limited number of the elevated reef terraces yielded coral samples suitable for age determinations, all terrace levels recognised in the field are indicated in Table 1, to aid in the interpretation and correlation of dated terraces. The ages were calculated from the measured $^{230}\text{Th}/^{234}\text{U}$ ratios, assuming initial isotopic activity ratios of $^{234}\text{U}/^{238}\text{U} = 1.15$ and $^{230}\text{Th}/^{234}\text{U} = 0^{2,11-14}$. The ^{232}Th present in the corals was negligible, and no corrections have been made for possible secondary addition of common ^{230}Th .

On Malo Island, 40 km north of Malekula, five raised reefs are gently tilted to the east¹⁰. Four of these raised reefs are present along an east-trending track near Ana settlement and two raised reefs have provided ages. Another sample, Ma 1, collected from a track between Abountari settlement and Pic Malo is probably the same age as the highest raised reef on the Ana sequence. Unlike Malo, North-West Efate is cut by several late

Quaternary faults which trend westerly and north-westerly¹⁵. A Holocene raised reef is mapped¹⁵ and above this at least three raised reefs are recognised on air photographs between Creek Ai and the air strip. One of the samples (Efate X) is from the much dissected highest raised reef and samples Efate 235 and Efate 180 from north-west of Port Havannah, lie adjacent to a late Quaternary fault on the 'upthrow' side. Because of poor exposures and late Quaternary diastrophism, then, correlation of raised reefs developed in the New Hebrides is not yet possible. Also using altimeters for height measurement can lead to significant errors. Age assignment to undated raised reefs on the basis of sea-level maxima recognised elsewhere is therefore not reliable, and has not been attempted here.

There is little doubt, however, that the terrace represented by Malo LT-1 and Efate 20 corresponds to reef complex I of Huon Peninsula, dated at 5,000 to 9,000 yr¹⁴. Similarly, the raised reefs represented by samples Efate 330 and Ma 1, both dated at 134,000 yr, and Efate X and Efate 235 both dated at about 120,000 yr may well correspond to sea-level stands VIIa (140,000 yr) and VIIb (120,000 yr), respectively, of Huon Peninsula^{13,14}. The ages of Efate 330 and Ma 1 are judged to be more reliable than those of Efate X and Efate 235, on the basis of mineralogical criteria used in the evaluation of dated

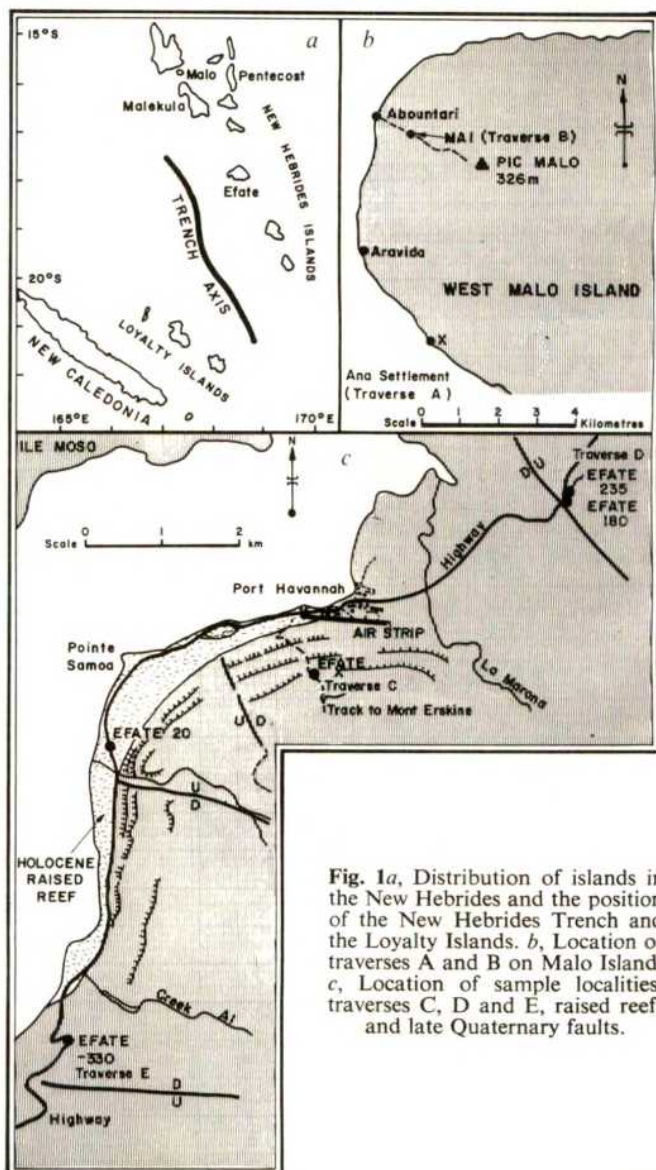

Fig. 1a, Distribution of islands in the New Hebrides and the position of the New Hebrides Trench and the Loyalty Islands. b, Location of traverses A and B on Malo Island. c, Location of sample localities, traverses C, D and E, raised reefs and late Quaternary faults.

Table 1 Raised reef elevations and radiometric ages of dated samples

Traverse	Elevation of terrace (m)	Sample no.	Calcite* (%)	U (p.p.m.)	U^{234}/U^{238}	Th^{230}/U^{234}	Age ($\times 10^3$ yr)

The errors shown are based on counting statistics ($\pm 1\sigma$).

*Based on X-ray diffraction analysis of representative coral sample after mechanical cleaning with dentist drill and/or ultrasonic vibration.

†Range in elevation between front and back of terrace.

‡Contained void filling micrite cement before clean-up.

samples^{2,14}. Efate X and Efate 235 may be suspect, the former because of its relatively high calcite content, suggesting incipient recrystallisation, the latter because it contained some secondary micrite cement which may not have been completely removed during the mechanical clean-up procedure. Furthermore, a distinction between the two age groups solely on the basis of radiometric ages may not be warranted, considering that the ages are not significantly different at the 95% confidence level. Two separate and stratigraphically well defined transgressions at 134,000 yr and 119,000 yr have also been recognised on the island of Atauro, north of Timor², supporting the view that the '125,000 yr sea-level stand' may in fact be the mean of two closely spaced, yet separate, stands of roughly the same elevation, the recognition of which depends on uplift rate and/or stratigraphic definition of a given raised reef sequence^{2,16,17}.

Because our data are limited, with only one age determination per individual terrace site, or none at all, we are not yet prepared to discuss the fine structure of palaeosea level in the New Hebrides over the past 140,000 yr. The ages given here for several of the raised reefs are useful, however, as they provide a more realistic time base for the late Pleistocene tectonic history of the area than has so far been available. For example, previous age estimates of the raised reefs on Malekula were obtained by assuming that the highest of the six tilted raised reefs present corresponds to the interglacial following the first cold period of the Pleistocene, hence it should be ~2 Myr old, with the ages of the other raised reefs, in descending order, calculated to be 1.8, 1.5, 1.0, 0.6 and 0.4 Myr on the basis of a steady uplift rate⁸. Mallick and Neef⁹ considered these age estimates far too old in comparison with the eustatic sea-level data from dated raised reefs on Huon Peninsula, a view which is supported by our much younger ages for terraces of similar elevation on nearby Malo Island, lying only 40 km from north-west Malekula.

The question of uniform or non-uniform uplift rate with time at a given location cannot be resolved without further field work and additional age determinations in the New Hebrides.

We propose that the mean uplift rate over the past 140,000 yr was at least 0.67 m per 1,000 yr on Malo, and between 0.55 and 0.77 m per 1,000 yr on North-West Efate—based on the data shown in Table 1 and the best estimates of palaeo sea levels at 120,000 and 134,000 yr (refs 2, 17). These values are not substantially different from those determined by similar methods in other active island arcs and orogenic belts along zones of lithosphere plate convergence^{1,2,11,13,14} but significantly higher than the uplift rate of 0.13 m per 1,000 yr estimated for the pre-subduction bulge west of the New Hebrides Trench⁴.

We thank Dr D. I. J. Mallick for advice on potential sample locations and Mrs G. Halliday for drafting Fig. 1. Financial assistance to G.N. was provided by the University of New South Wales and the Mine Managers' Association of Broken Hill and to H.H.V. by the Australian Research Grants Commission.

New evidence and possible origin of native iron in ophiolites of eastern Canada

THERMOMAGNETIC analysis has been used to detect traces of submicroscopic elemental iron in four bodies of Early Palaeozoic oceanic metabasalt (Fig. 1). The initial finding of iron in Newfoundland ophiolites¹ is believed to be the first terrestrial discovery of native ferromagnetic metal through magnetism. A few rock samples in these four areas have unusually high Curie points indicating pure or nearly pure iron. In one basaltic pillow, previous magnetic evidence² was confirmed by electron microprobe showing very fine Fe particles embedded in chlorite. We propose that such particles formed by reduction of olivine under water and became trapped in the chlorite host. Although native iron seems rare on Earth^{3,4}, further suboptical discoveries through rock magnetism may be predicted. Such findings could prove valuable in identifying ancient oceanic crust generated in a reducing environment.

Fig. 1 Ophiolites and related rocks in Quebec and Newfoundland. A, Asbestos; BV, Baie Verte; G, Gander River; MB, Ming's Bight; O, Orford; P, Pilleys Island. Bodies in which native iron was identified are numbered: 1, Thetford Mines; 2, Betts Cove; 3, Hare Bay; 4, Moreton's Harbour.

The Thetford Mines⁵ and Betts Cove⁶ ophiolites (Fig. 1, areas 1, 2) are closely similar⁷. The former is middle Cambrian or older and was emplaced in the early Ordovician⁵, while Betts Cove may have originated and been emplaced somewhat later^{8,9}. The early Ordovician^{10,11} transported ophiolite at Hare Bay (area 3) lacks gabbro and sheeted dikes. At Moreton's Harbour (area 4) an 8-km thick volcanic sequence is attributed¹² to Ordovician island arc volcanism. No iron has been detected outside of areas 1–4, nor in gabbros or ultramafics.

Curie points (T_c) were obtained from curves of high-field magnetic moment plotted against temperature ($M-T$). Powders were heated in vacuum² or air¹³ to 800 or 900 °C (Fig. 2a, c–e). Also initial susceptibility variation with temperature ($K-T$) of whole rock was measured in air¹⁴ (Fig. 2b). Iron contamination

can be ruled out as all specimens were prepared by rigorously avoiding contact with ferromagnetic materials.

Two of the heating curves (Fig. 2a, b) indicate magnetite, but all five show high T_c values in the range 755–775 °C. This corresponds to¹⁵ the Curie point of α -iron (770 °C) or of iron alloyed with less than 5% nickel (770–750 °C). The trends of the irreversible curves obtained in air seem to be better explained by oxidation of iron, initially to magnetite, than by α , γ phase transitions¹⁵. Figure 2c, d resembles curves for lunar samples which likewise may have been oxidised, though heated in a vacuum^{16,17}. The smaller saturation magnetisation of magnetite ($4.80 \times 10^5 \text{ A m}^{-1}$) than of iron ($17.0 \times 10^5 \text{ A m}^{-1}$) is consistent with this. Still, some samples became more magnetic upon cooling (Fig. 2b, c). Lunar samples (see ref. 17) show similar variations which suggest that grain-size effects are important. The large susceptibility increase on cooling in Fig. 2b may be due to superparamagnetic magnetite produced by heating the iron¹⁷.

Table 1 shows values of natural remanence, susceptibility and Koenigsberger ratio of Thetford Mines pillows. For any pillow zone the mean values are respectively three, one and two orders of magnitude less than world-wide averages for young drilled deep-sea basalts¹⁸. Low, widely variable Koenigsberger ratios (0.5 to 0.001) predominated also in Newfoundland. Very unevenly distributed secondary magnetite and/or iron could account for these findings.

Estimated elemental iron in samples does not exceed a few tenths of one weight percent. At Thetford Mines, iron was detected in 13 out of 51 thermomagnetic analyses made on 14 pillows (Table 1), with mean Curie point 756 ± 4 °C (standard deviation). In Newfoundland, 28 samples each had yielded at least one $M-T$ curve showing significant iron (total 56 analyses). Mean Curie points are: Betts Cove pillows, 760 ± 11 °C (15 samples); Betts Cove dikes, 759 ± 7 °C (four samples); Hare Bay pillows, 761 ± 11 °C (six samples); Moreton's Harbour pillows, 750 ± 5 °C (three samples). Three reliable $K-T$ curves, for Hare Bay (Fig. 2b) and Betts Cove, gave $T_c = 760-775$ °C.

At Laval University a Thetford Mines pillow that had produced $M-T$ curves similar to Fig. 2a was shown by electron microprobe to contain small ($< 5 \mu\text{m}$), lamellar particles of 96–98% pure Fe: also chalcopyrite, sphene, magnetite and chromite. The opaques occur as minute inclusions in the fractures of former olivine microphenocrysts entirely pseudomorphosed by magnesian-chlorite. A single iron particle was just large enough to be seen with the reflecting microscope. In four samples from areas 2–4 in Fig. 1 having 'iron' but not 'magnetite' Curie points, microprobe analysis showed abundant sulphides, also sometimes limonite, hematite, iron oxyhydroxides or sphene, but neither magnetite nor Fe. This is compatible with the presence of extremely fine-grained iron.

Terrestrial nickel and iron has been described from less than 24 localities^{3,4} where nickel-iron containing 65–75% Ni always occurs only in serpentinised ultramafics. Nickel-poor iron ($> 90\%$ Fe), however, usually occurs in mafic rock^{3,4,19–22}. A second significant fact is that, wherever we inferred iron, the pillow lava or dike rock has undergone greenschist metamorphism. The pillow lava is of two types²³, a dark splititised metatholeiite rich in chlorite and a light green olivine metatholeiite rich in actinolite and chlorite pseudomorphs. At Thetford Mines, but not Betts Cove, native iron seems to be confined to the olivine metatholeiites².

Table 1 Magnetic properties and ferromagnetic constituents according to pillow zones (Thetford Mines, Quebec)

Pillow zone	<i>n</i>	$J_n (\times 10^{-3} \text{ A m}^{-1})$		$K (\times 4\pi \times 10^{-6})$		Range Q_n	Mean	n_M	n_{Fe}
		Range	Mean	Range	Mean				
Margin	15	1.15–4.25	1.95	18.0–57.3	45.2	0.03–0.13	0.05	15	0
Intermediate	22	0.56–3.26	1.42	19.9–35.9	31.1	0.05–0.14	0.08	22	9
Core	14	0.78–4.41	1.81	12.5–33.3	25.0	0.07–0.27	0.12	14	4

n, No. of whole-rock specimens (total 51) cut from 14 samples of pillow lava; J_n , intensity of NRM; K , initial susceptibility; $Q_n = J_n KH$, natural Koenigsberger ratio, where H is the Earth's present field. Geometric means are quoted. One powder per whole-rock specimen was prepared for thermomagnetic analysis to identify the magnetic constituents (Fig. 2a, ref. 2); n_M , n_{Fe} , number of analyses indicating magnetite or (additionally) iron. Note that magnetite is inferred in all powders.

Fig. 2 Thermomagnetic curves for pillow lava from areas 1-4 (Fig. 1), normalised to 25 °C before heating. Specimens were heated and cooled in a vacuum of 10^{-3} torr (a) or in air (b-e). b, K - T curves (see text) for whole rock fragments up to 1 cm diameter, measured in a peak field $H = 0.031$ mT. a, c-e are M - T curves for coarse powders up to 1 mm, measured in fields of 0.10-0.13 T. Curie points (T_c) were obtained to better than ± 15 °C and are quoted to 5 °C. a, Thetford Mines, intermediate zone of pillow A (Table 1, ref. 2), showing two-component M - T curves, $T_c = 580$ °C, 755 °C. b, Hare Bay, intermediate zone of pillow HB 1, showing two-component K - T curves: $T_c = 595$ °C, 770 °C. c, Hare Bay, intermediate zone of pillow HB 1, M - T curves, $T_c = 770$ °C. d, Betts Cove, core of pillow BC 9, M - T curves, $T_c = 775$ °C. e, Moreton's Harbour, small pillow MH 33, M - T curves: $T_c = 755$ °C.

The iron could have originated (1) as dusts with magnetite in the rock ground-mass; (2) as reaction product between magnetite and iron sulphide in the ground-mass; or (3) as by-product of alteration of the olivine microphenocrysts. Mode (1) was not confirmed by microprobe and in any case the tiny, unprotected iron particles would have been rapidly oxidised. Mode (2) also seems unsupported since the iron identified by microprobe occurs without sulphide-magnetite; in the Newfoundland samples Fe tends to occur without magnetite; the association sulphide-magnetite is frequent in basalts while native iron is rare.

Alternative (3) assumes a paragenetic relationship between olivine and native iron. During serpentinisation of olivine, iron-related redox mechanisms may have controlled the formation in serpentine of magnetite and nickel-iron in equilibrium⁴. Serpentinisation itself might generate a highly reducing environment by the dissociation of water to provide the oxygen required to form magnetite, thereby releasing hydrogen^{24,25}. The same process can tentatively be applied to chloritisation of olivine in our rocks. The equilibrium assemblage resulting from the reaction

would comprise the minerals that actually replaced the olivine phenocrysts in the pillow lava. With sufficient hydrogen the magnetite can be further reduced to iron and water, which may explain its paucity in Newfoundland samples. The iron encapsulated in chlorite crystals would be protected against oxidation as long as the chlorite remained unaltered.

If this explanation is correct, then elemental iron should occur also in rocks of similar genesis elsewhere; for example, Curie points suggesting Fe have been reported²² from the greenschist facies of Archaean metavolcanics. Because of typically minute grain sizes, rock magnetism remains the most promising method for discovering native ferromagnetic metal.

Mesozoic sea floor off Dronning Maud Land, Antarctica

THE accreting margin between the African and Antarctic plates is now well understood between the Bouvet triple junction and Marion Island (Fig. 1). Published data obtained from the ridge axis near 1°W^1 , 15°E^2 , and 36°E^3 can be combined to yield a relative rotation pole at 11°N , 41°W with an equatorial half spreading rate of 0.8 cm yr^{-1} . Away from the spreading axis, very little is known apart from a narrow region to the north in the Mozambique Basin where Bergh and Norton³ have shown that the present spreading regime commenced at least as far back as the Late Cretaceous. This is the only region where transform fault traces have been extended for more than 100 km from the spreading centre and where magnetic lineations have been related to the present tectonic pattern. I describe here a group of lineations recently mapped in the Antarctic Basin off Dronning Maud Land, interpreted as being due to sea floor generated at the South-west Indian Ocean Ridge in the Early Cretaceous.

Two curtailed excursions in this area were carried out during the summers of 1976 and 1977. Figure 2 shows magnetic anomalies plotted perpendicular to ship's tracks. Anomaly identification was made by projecting the profiles on to 30°E (Fig. 3) and comparing with simulated profiles based on the reversal timescale of Larson and Hilde⁴. The Mesozoic sequence M-1 to M-9 (113 to 121 Myr.) is considered to be well matched, with M-2, M-4 and the diminutive M-6 showing up clearly. A spreading rate change from 2.0 to 1.5 cm yr^{-1} at anomaly M-5 time is apparent from the matching to the two theoretical profiles in Fig. 3. Anomalies older than M-9 are included only tentatively in the present interpretation.

The area surveyed is characterised by a generally featureless bottom topography with the regional depth sloping from 4 km at about 68°S to 5 km at 64°S . Limited seismic reflection profiling has revealed a flat-lying acoustic basement with sediment thickness of about 1.6 s of double travel time. A striking basement outcrop of up to 2 km above the surrounding sea floor is indicated by lineament F in Fig. 2. Its strike of 30° , based on three crossings, is exactly perpendicular to the mean azimuth of the observed magnetic lineations. Sea-floor depth is distinctly different on either side of this presumed fracture zone and is consistent with the expected older sea floor being on

Fig. 1 Survey area (stippled) in Antarctic Basin. The South-west Indian Ocean Ridge and its junction with the Mid-Atlantic Ridge are shown schematically by double lines (sections of spreading ridge) and single lines (fracture zones and active transform faults). B, Bouvet Island; M, Marion Island.

the eastern side. A major west-facing fault scarp between 30° and 33°N in the Mozambique Basin, associated with Late Cretaceous spreading³ along the South-west Indian Ocean Ridge, is approximately co-polar (rotational) with fracture zone F, and has a similar depth contrast (500 m) across it. This is greatly in excess of calculations based on depth against age of ocean floor and could be related to a spreading style in which the two inward-facing walls of a deep transform fault crack move in opposite directions. The minor lineament f in Fig. 2 marks the eastward termination of identifiable magnetic anomalies, as indicated on profiles D and E in Fig. 3.

Magnetic anomaly and fracture zone trends reported here are consistent with their being initiated at the presently active ridge near Marion Island. More data will, of course, be required

Fig. 2 Total field magnetic anomalies plotted perpendicular to ship's tracks after removal of International Geomagnetic Reference Field. Positive anomalies in black. Lineaments F and f were based respectively on a prominent basement ridge and the eastward termination of identifiable anomalies. Portion S-S' of profile C was surveyed during a magnetically disturbed period. Navigation by satellite and VLF Omega.

between the ridge and the M-sequence of anomalies before an unequivocal tie-in can be demonstrated. In Fig. 4 anomalies M-1 to M-9 as well as the lineaments F and f have been rotated by 20.5° about the present Africa-Antarctica rotation pole to bring anomaly M-1 close to the active accreting margin. Fault scarp F is nearly co-linear with the first fracture zone to the west of the Prince Edward fracture zone while lineament f coincides with an area of present dubious ridge signature which Bergh and Norton³ suggest might be an incipient transform fault. The ridge sections shown in Fig. 4 are based on data obtained subsequent to that included in their paper. The short section across 36°E is almost orthogonal to the Prince Edward fracture zone and is separated from the definitely oblique section ($37-38^{\circ}\text{E}$) by a nearly 50-km wide region where no central magnetic anomaly is apparent. The close correspondence between present and Mesozoic spreading might be fortuitous—it might also point to a persistent localised upper mantle property.

Fig. 3 Magnetic anomalies projected on to assumed spreading direction (Profiles A to E) and theoretical profiles for half spreading rates of 1.5 and 2.0 cm yr⁻¹. Simulations and anomaly numbering were based on the Larson and Hilde⁴ reversal time-scale with two-dimensional blocks of magnetised (1000 nT) sea floor trending 120° between depths 4.5 and 5.0 m. Vertical bars on profiles D and E mark the termination of identified anomalies and form the basis for the lineament f in Fig. 2.

As a working hypothesis, it is reasonable to assume that rifting along this segment of the ridge has proceeded in a remarkably stable way since the Early Cretaceous. Spreading rates have varied considerably and sections of ridge have changed orientation³ but the average pole describing the relative plate motion is very close to the present pole. Extrapolation of the Mesozoic spreading rate and direction back to the 2-km isobath off Dronning Maud Land dates the onset of spreading as roughly 150 Myr. or Late Jurassic. This slightly pre-dates estimates^{5,6} of the initial rifting of eastern Gondwanaland and is in very good agreement with the proposed early separation rate⁵ for that region.

Unusual diatom off the coast of south-west England and its effect on fishing

AN unfamiliar diatom was observed in the local townnettings taken by research vessels of the Plymouth Laboratory towards the end of January 1977. It was a large member of the genus *Coscinodiscus*, but a species not previously known in the English Channel. The mucilage produced by this diatom was so abundant as to restrict trawling in some areas off Plymouth.

The valve pattern of the diatom resembled that of some forms of *Coscinodiscus concinnus* Wm Smith¹ with the valve having a clear centre, but the diameter was greater than that recorded for *C. concinnus* in the English Channel. It was unlike any other species of *Coscinodiscus* recorded for the western English Channel in that the 50-μm deep valve mantle met the valve face at right angles. As the valve itself was almost flat the diatom had a markedly rectangular outline in girdle view. A search of the literature showed that this diatom was probably *Coscinodiscus nobilis* Grunow. Our material agrees essentially with the description and illustration of *C. nobilis* given by Simonsen² and it agrees with the material of Grunow designated as lectotype by Simonsen². Grunow³ described this species from the Java Sea and it has only otherwise been recorded from the

Indian and Pacific Oceans⁵, although there are two doubtful records from the east coast of England⁶ and one from Heligoland⁷.

As the diatom was apparently increasing in numbers near Plymouth sampling was initiated in which 10 l samples were poured through a tynet of 170- μ m mesh and the trapped diatoms counted. The diatom was successfully cultured in the laboratory and it divided every 2 d at 18 °C and every 3 d at 13 °C. In culture this diatom produced much more mucilage, which collected on the bottom of the culture vessel, than other species of *Coscinodiscus* we have cultured in similar conditions. Workers on our research ships complained that townets were becoming clogged with mucilage during sample collection.

During a hydrographic and biological cruise in the western English Channel on 19–21 April, the distribution of the diatom was plotted from tynet samples (Fig. 1). On 1 May 1977 Dr A. J. Southward took a sample from 48°13'N, 08°11'W which was rich in this diatom, showing that it was abundant further west than we had sampled.

By the end of April the Fishery Officer at Plymouth was receiving complaints from the Plymouth fishermen that their trawls were becoming clogged or broken by a very heavy grey slime. The slime made hauling difficult and prolonged washing or air drying did not completely remove it. The slime was most prevalent on the sea bed in areas where the unusual diatom was most abundant.

Light microscopy showed that the slime was heavily loaded with clay particles and the insoluble remains of plankton organisms, such as the skeletons of silicoflagellates. The slime and the mucilage from the diatom were shown to be of the same chemical structure.

The diatom had reached high numbers for a cell of this size and had produced copious mucilage which, in sinking, had accumulated the insoluble skeletons of plankton organisms and, on the sea bed, had collected mineral particles which increased its volume and density. From our cultures we estimated that for a given volume of cells, there was two to three times the volume of mucilage present. Counts from seawater samples

taken off Plymouth were about 100 cells per l for several weeks in April. As the water column was completely mixed at that time, we assume that the diatoms were distributed through the whole 50 m of the water column. With a mean cell volume of 0.01 mm³ per diatom, 150 ml of slime could accumulate on each square metre of seabed. The slime would be concentrated in certain areas of the seabed by tides and the act of trawling would also accumulate it until it caused inconvenience to the fishermen. If a trawl with a 16 m spread were towed at 3 knots for 1 h it could sweep up about 5 m³ of slime. Even if more than half the slime passed through the net the accumulation on a 3-h tow would be considerable. Furthermore, although slime would pass through the net initially, once it had started to adhere to the meshes the percentage retained would increase rapidly. The volumes given here are minimal as the calculations are based on the mucilage produced by the diatoms and the accumulation of large quantities of bottom material in the slime would considerably increase its volume and density.

There are two published records of exotic diatoms appearing in European waters and forming a major part of the phytoplankton. *Biddulphia sinensis* Grev. was described from the China Sea⁸ and its first arrival and subsequent spread was recorded⁹. This species is now a prominent contributor to the winter and spring phytoplankton of the western English Channel. The second species, *Pleurosigma planctonicum* Simonsen, was first described² from the Indian Ocean. Simonsen collected his material in 1964–65 and we found this species in the western English Channel in 1966 (ref. 10). *Pleurosigma planctonicum* became dominant in the Plymouth area in 1973 and is still present in the English Channel, although its occurrence is sporadic. In neither case were there any reported effects other than the displacement of native species by the new arrivals.

We cannot offer an explanation as to how *Coscinodiscus nobilis* reached the English Channel. By mid-May, numbers had declined, although the species had not completely disappeared, and, by the end of May, there were no reports of slime clogging nets. Whether this diatom together with the inconvenience to trawling caused by its mucilage will become a regular feature of the spring phytoplankton in the English Channel remains to be seen.

We thank Dr Elizabeth Percival of Royal Holloway College, London, for analysing the mucilage and slime, Mr C. Knott and the crew of R.L. Gammarus for taking samples, Dr A. J. Southward for samples from RRS Shackleton and Mr W. Williams, District Fishery Officer, Plymouth, for information on the occurrence of the slime on the fishing grounds.

Pattern regulation and transdetermination in *Drosophila* imaginal leg disk reagggregates

WHEN *Drosophila* imaginal disk tissue is cultured *in vivo*¹, the proliferating cells can adopt new fates within the limits of a single disk ('pattern regulation'^{2,3}) or may even produce structures normally derived from a different disk ('trans-determination'⁴). Much of the pattern regulation occurring in

imaginal disk fragments may be controlled by interactions between cells that come together during wound healing^{3,5}. I report here further studies on the role of cell interactions in pattern regulation and transdetermination, by means of dissociation and reaggregation of specific disk parts. The data confirm the importance of cell interactions for pattern regulation, and suggest that interactions between cells with large positional disparities may also be crucial for the stimulation of transdetermination.

We have previously studied pattern regulation and transdetermination in non-dissociated male foreleg disk quadrants (ref. 6 and unpublished results), and in identical fragments which were dissociated together with an excess of heavily irradiated wing disks ('feeding layer') and then cultured as 'mixed reaggregates'⁸.

In intact fragments, distal transformation⁹ (as judged by the regeneration of claws, which represent the distal tip of the adult appendage; Fig. 1a) occurred only in UM^- and, with a lower frequency, in LM^- quadrants (Table 2; for abbreviations see Fig. 1), whereas in mixed reaggregates, cells from all four quadrants frequently underwent distal transformation. Furthermore, although among the intact fragments only the UM^- quadrants transdetermined, cells from UM^- and UL^- quadrants underwent extensive transdetermination in mixed reaggregates. Since LM^- and LL^- cells failed to transdetermine in either situation, the hypothesis was advanced that only certain cells in the upper half of the male foreleg disk are capable of transdetermination¹⁰ (Fig. 1b). The more frequent distal transformation and transdetermination in mixed reaggregates could not be explained, however. It seemed possible that the initial destruction of the tissue organisation had caused both events, but I show here that they were stimulated mainly by interactions of the leg disk cells with 'feeding layer' cells present in the mixed reaggregates.

Drosophila male foreleg disk quadrants were dissociated, reaggregated, and cultured as 'pure reaggregates' (that is, without 'feeding layer'). In each experiment 120 quadrants (lacking most of the presumptive tarsal material; Fig. 1a) from third instar disks were dissociated with a microstirrer in a 0.05% trypsin solution⁷. The degree of dissociation varied as reported earlier⁸, clumps comprising up to about 20 cells occurring regularly. The reaggregated cell mass was divided and injected into fertilised adult females and cultured for 8 d at 25 °C. The implants were then transplanted into host larvae for

metamorphosis. Since most implants had to be cut into several pieces for this injection, the average number of larvae injected with material from one adult host represents a rough measure of the proliferative activity of the cells (Table 1). The death of injected larval hosts meant that a variable amount of material was lost in every experiment (Table 1). The differentiated implants consisted of a mass of vesicles, with each vesicle usually containing structures of a single leg segment. The number of vesicles typical for each leg segment was determined, and the cuticular landmarks (Fig. 1a) were scored. The implants were also examined for transdetermined structures. The data are presented in Table 1; Table 2 summarises the data available (refs 6, 8, 11, and this study) on pattern regulation and transdetermination in the male foreleg disk following different experimental treatments.

The main findings for pure reaggregates are (Table 1): (1) Distal transformation, as judged primarily by the regeneration of claws, but also by a comparison of the number of vesicles per leg segment (compared with control experiments, Table 1b), was very rare, even in UM^- reaggregates; (2) Regeneration of structures missing in a circumferential direction occurred rarely, if at all, in LM^- , LL^- and UL^- reaggregates, and even in UM^- reaggregates only a few cases were observed; (3) Transdetermination was only observed in UM^- reaggregates, where two small wing-blade spots were found; (4) The rate of proliferation of the LL^- cells was very low, confirming earlier findings^{6,8}.

The rarity of both distal transformation and transdetermination in pure reaggregates contrasts sharply with the behaviour of identical leg disk cells in mixed reaggregates (Table 2). The data indicate that the high frequency of both events in mixed reaggregates did not result from the dissociation procedure *per se*, but rather from interactions between leg disk cells and 'feeding layer' cells. A specific effect of the irradiation of the 'feeding layer' cells on leg disk cells was ruled out by experiments in which UM^- quadrants were dissociated together with unirradiated wing disks. Both distal transformation and transdetermination were frequent in such reaggregates (Table 1b, D). The disk type of the 'feeding layer' tissue was also irrelevant to the behaviour of the leg disk cells. In mixed UL^- reaggregates containing either antenna disk or male foreleg disk 'feeding layers' (Table 1b, B, C) distal transformation and transdetermination occurred frequently, and the transdetermined structures were almost exclusively of wing disk type, as with

Fig. 1. a, Simplified fate map of the *Drosophila* male foreleg disk (after Schubiger¹⁸). Leg segments: PT, prothorax; CX, coxa; TR, trochanter; FE, femur; TI, tibia; TA, tarsus. Cuticular landmarks: Δ , groups of sensilla trichodea (St1, St8, GST, St5, RSt); \circ , groups of sensilla campaniformia (Sc1, Sc5, Sc11, Sc3, Sc8); \bullet , single conspicuous bristles (BH⁻, EB), or sex comb teeth (Sct); JTr, JTh, joints; Tvr, transverse rows of bristles; Cl, claws. — — —, location of cuts. UM^- , LM^- , LL^- , UL^- , upper medial, lower medial, lower lateral and upper lateral quadrants, respectively, lacking their corresponding 'endknob' parts (which contain most of the tarsal material^{11,15}). UM^- , LM^- , LL^- , UL^- in the text indicate that experiments with quadrants both containing and lacking their 'endknob' portions had been carried out. b, Polar coordinate model specifying positions in the *Drosophila* male foreleg disk (modified⁶ after French *et al.*³), and approximate location of the cells capable of transdetermination in the disk¹⁰ (hatching). 1–12, Circumferential positional values; A–E, radial positional values.

reaggregates containing wing disk 'feeding layer'⁸. It thus seems that cells from different imaginal disks exert similar effects on pattern regulation and transdetermination in intermixed leg disk cells.

In pure reaggregates, the cells of all quadrants chiefly formed structures characteristic for their region of origin (Table 1). This indicates that dissociated cells and cell clumps retain their positional information⁷. The mixed reaggregates, however, clearly show that these cells or cell clumps can, in appropriate conditions, be stimulated to acquire specific new developmental programmes. What factors caused identical cells to behave differently in different experimental conditions? The polar coordinate model of French *et al.*³ postulates that pattern regulation in *Drosophila* imaginal disks is controlled by interactions among cells carrying disparate positional information², brought into contact by wound healing or mechanical intermixture. Such disparities are thought to induce proliferation which, in accordance with specific rules, leads to the intercalation of missing positional values. According to this model the regeneration of a complete field circumference, as well as distal transformation, are possible only if a blastema possesses the majority of the circumferential positional values. Since in mixed reaggregates cells from all quadrants underwent distal transformation, the possibility was considered that the pattern regulation rules might not apply in reaggregates⁸. The rarity of distal transformation in pure reaggregates (Table 1), however, indicates that this is not the case, and suggests that the rules are still followed by dissociated and reaggregated cells and cell clumps. (It should be noted, however, that the polar coordinate model cannot explain the rare cases of distal transformation in pure *LM*⁻ reaggregates, nor the observed instances of distal transformation in intact *LM*⁻ quadrants and lateral halves; see Table 2 and ref. 11.) A more likely explanation for the behaviour

of the leg cells in mixed reaggregates is that they interacted with 'feeding layer' cells possessing non-homologous positional values⁸. In this way, complete circumferential sequences of positional information could be generated and allow distal transformation to occur. Evidence for communication between non-dissociated leg and wing disk tissues, resulting in the stimulation of intercalary regeneration⁵ in intermixed fragments (highly irradiated fragments being as effective in stimulation as unirradiated ones¹²) has now been obtained (ref. 13, and unpublished results of P. Adler, M. Fain and S.S.). These findings thus support the concept of a common mechanism of positional specification in different imaginal disks^{2,3,14}.

The high regenerative potentials of intact *UM*⁻ fragments led to this disk region being ascribed the majority of the circumferential positional values³ (Fig. 1b). Pure *UM*⁻ reaggregates, however, showed only rare regeneration (Table 1), a disparity which can be explained in terms of the polar coordinate model³. In intact *UM*⁻ fragments, wound healing always juxtaposes the two radial cut surfaces^{3,15}, thus creating the conditions necessary for the intercalation of the missing circumferential values ('shortest intercalation rule'), followed then by distal transformation ('complete circle rule'). In pure *UM*⁻ reaggregates, however, the cells have to become confronted by chance with cells showing a positional disparity corresponding to about half of the circumferential values, in order to regenerate complete circles which could then permit distal transformation. Clearly, the probability of such an event is quite small, especially since the *UM* region probably possesses only slightly more than half of the circumferential values⁶. In mixed reaggregates, however, cells from all quadrants would frequently confront 'feeding layer' cells that have sufficiently disparate positional values to allow the formation of complete circles followed by distal transformation.

A similar mechanism could also explain the differences in transdetermination frequencies using different treatments (Table 2). According to a recent hypothesis¹⁰, transdetermination occurs when cells capable of it (Fig. 1b), by juxtaposition with cells having sufficiently different positional values, are stimulated to a certain critical amount of proliferation. In intact UM⁽⁻⁾ fragments, the fusion of the radial cut surfaces regularly confronts the cells capable of transdetermination with cells having nearly maximal disparities in circumferential values. The amount of intercalary growth thus induced would often trigger transdetermination. In pure UM⁻ reagggregates, however, the chance for the transdetermination-competent cells to confront cells with positional disparities large enough for the stimulation of transdetermination is very small. In intact UL⁽⁻⁾ fragments and in pure UL⁻ reagggregates, the cells capable of transdetermination simply could never meet cells with a positional disparity sufficient for the stimulation of transdetermination, because of the low density of circumferential values in this disk region^{3,6}. In mixed UM⁽⁻⁾ and UL⁽⁻⁾ reagggregates, however, juxtaposition to 'feeding layer' cells with large disparities in positional values would often cause a sufficient amount of proliferation in the cells capable of transdetermination to stimulate them to undergo this change. Earlier reports of sharply increased transdetermination frequencies in imaginal disk reagggregates^{16,17} can similarly be explained by cell interactions of this kind, without having to assume a specific effect of the dissociation procedure *per se* ('wounding effect') on transdetermination.

I thank Suzanne Glenn and Becky Hsei for technical assistance. I was supported by a fellowship from the Swiss National Science Foundation and by a grant from the United States National Institutes of Health.

Haemopoietic stem cells of rats but not of mice express Th-1.1 alloantigen

IN mice thymus-derived lymphocytes express θ -antigen specificities in two allelic forms, Th-1.1 (formerly called θ -AKR) and Th-1.2 (θ -C₃H), which are distributed reciprocally among the various mouse strains^{1,2}. Rats have also been tested for the occurrence of antigens of the Th-1 system, but so far all strains have been positive with anti-Th-1.1 only^{3,4}. Rats also differ from mice in the concentration of Th-1.1 carrying cells, which, in rats, is much higher in the bone marrow and lower in the peripheral lymphoid organs⁵. The stage at which haemopoietic stem cells differentiate towards thymocytes carrying the θ alloantigen is still ill-defined. We present here evidence that in rats Th-1.1 is already expressed on haemopoietic stem cells while murine haemopoietic stem cells have not yet developed this θ alloantigen.

Haemopoietic stem cells are defined operationally by their capacity to form cell colonies⁶, proliferate in diffusion chambers⁷ and, of course, repopulate a conditioned bone marrow recipient. The latter activity can be inhibited by sensitising the prospective bone-marrow recipient against antigens occurring on the donor's stem cells or by incubating the donor's marrow with antibodies against his stem cells before transferring it to the recipient. Both experimental models served as indicator systems for Th-1 antigens on stem cells in the following experiments.

Mouse strains CBA, C₃H, (C57BL/6 × CBA-T6)F₁, A and BALB/c, all Th-1.2 and AKR (Th-1.1) were obtained from The Jackson Laboratory, Bar Harbor, Maine and AKR/Cum (Th-1.2) mice from Cumberland View Farms, Clinton, Tennessee. The two AKR sublines are antigenically similar with respect to markers Ly-1, Ly-2, Ly-3, TL, H-2, G_{IX} and Gross cell surface antigen, while differing for Thy-1⁸. A/ θ AKR (Th-1.1) mice were produced from mice originally supplied by Dr E. A. Boyse of the Sloan-Kettering Institute, New York. They are congenic to A/J and differ only at the Th-1 locus. Inbred Lewis rats were produced in our laboratory: 90% of their thymocytes were lysed by anti-Th-1.1 but not by anti-Th-1.2 in the microcytotoxicity test. These antisera had a cytotoxic titre of 1:512 and more and had been produced by

repeated immunisation of CBA, C₃H, AKR/J mice or Lewis rats with Th-1 incompatible thymocytes (10⁸ cells injected three times 5 d apart).

Failure of engraftment due to presensitisation against antigens on donor-type haemopoietic cells is a very sensitive indicator system. It reveals also minor antigen incompatibilities where serological *in vitro* tests fail⁹. To avoid any undesired cross-immunisation of the recipient from antigens on the donor's thymocytes other than Th-1.1, bone marrow recipients were immunised with thymocytes of third-party strains sharing the Th-1.1 antigen of the donor strain but no other tissue antigens which might prevent haemopoietic engraftment. Intraspecies sensitisation was therefore combined with interspecies bone marrow transplantation and vice versa. Interspecies xenogeneic bone marrow transplantation from rat to mouse (for conditions see Table 1 legend) regularly leads to complete chimaerism¹⁶. The following experimental design was used: prospective bone marrow Th-1.2 recipient mice were sensitised against Th-1.1 or Th-1.2 thymocytes of rats or different mouse strains. They were subsequently irradiated and transfused with third-party marrow from AKR/J or Lewis rats (both Th-1.1). Failure of engraftment was taken as evidence for sensitisation against alloantigens shared by sensitising cells and haemopoietic stem cells of the donor strain. Chimaerism was tested in the femora by chromosomal analysis in allogeneic chimaeras using the T6 marker chromosome and by selective alkaline phosphatase staining of rat granulocytes¹⁵ in xenogeneic chimaeras.

Experiments 1 and 2 in Table 1 show that immunisation with Th-1.1 thymocytes of A/θ AKR mice or Lewis rats did not interfere with a take of subsequently transferred AKR/J bone marrow. Control series of untransplanted mice of the recipients' strains receiving AKR/J or Lewis or A/θ-AKR thymocytes had regularly shown high titres (< 1:256). Rat bone marrow, in contrast, failed to grow in mice sensitised against the mouse Th-1.1 antigen. That this failure of engraftment is not inherent to the xenogeneic donor-recipient combination itself is shown in experiments 4, 6 and 8 where rat marrow grew easily in mice sensitised against thymocytes of congenic or allogeneic Th-1.2 strains.

Table 2 Chimaerism in mice after transfer of rat marrow pre-incubated with anti-Th-1.1 or anti-Th-1.2 serum

Incubation* with	Chimaerism on day 14†
Anti-Th-1.2 (AKR/J-anti-C ₃ H)	10/60, 5/95, 1/18, 0/10
Anti-Th-1.1 (C ₃ H-anti-AKR/J)	5/1, 4/0, 0/0, 0/0, 20/3, 20/0, 18/0
Normal mouse serum	0/100, 0/20, 3/0, 0/60, 0/100, 0/100, 2/98, 0/0
No serum	0/50, 0/3, 0/30, 3/17

*0.25 ml for 30 min at 37 °C.

†No. of alkaline negative mouse granulocytes per no. of alkaline positive rat granulocytes.

Chimaerism was an all-or-none phenomenon which occurred uniformly in all animals of an experimental group.

Group-specific stem cell toxicity of anti-Th-1.1 was also demonstrated by incubating rat marrow with anti-Th-1.2 (AKR/J-anti-C₃H) and anti-Th-1.1 (C₃H-anti-AKR/J) serum. Table 2 shows that only the latter antiserum prevented a take of the rat marrow, which was suggested by the absence of circulating rat granulocytes and proved by a completely aplastic bone marrow histology (Hoffmann-Fezer, unpublished) of the recipient mice. In contrast, transplantation of allogeneic bone marrow from AKR/J mice to (C57BL/6 × CBA-T₆)F₁ recipients was not inhibited by a pre-incubation of anti-Th-1.1 (CBA-anti-Lewis) serum (not shown in Table 2) though this antiserum reacted strongly with AKR/J (1:1024). The transfer experiments clearly show that sensitisation against Th-1.1 positive rat marrow either *in vivo* by immunisation of the marrow recipient against Th-1.1 mouse marrow or *in vitro* by incubation of the donor marrow with anti-Th-1.1, inhibits the repopulating capacity of haemopoietic rat stem cells. The immunogenetic specificity of this inhibition is evident because sensitisation against Th-1.2 in otherwise identical conditions did not inhibit haemopoietic repopulation of mice with rat marrow. It is difficult to preclude that a transplantation antigen closely linked to Th-1.1 rather than the θ antigen itself occurs on the rat's haemopoietic stem cells and prevents repopulation implying a tissue antigen occurring in rats and AKR/J but absent from AKR/Cum and the other Th-1.2 mouse strains tested: this seems unlikely, however.

On the other hand, the allogeneic cell transfer experiments also show unequivocally an absence of the Th-1.1 antigen on mouse haemopoietic stem cells. Stem cells of the Th-1.1 donors preserved the capacity to induce haemopoiesis in recipients in spite of an antiserum treatment inhibiting the Th-1.1 lymphocytes present together with the stem cells in the donor cell inoculum. That these stem cell-sparing anti-θ antibodies were active against the donor strain lymphocytes can be shown by their suppression of graft-versus-host reactions¹⁰.

The absence of the θ antigen from mouse stem cells is in agreement with reports on anti-mouse brain serum from rabbits, absorbed with B-cells, which spared haemopoietic stem cells and suppressed T cell-derived graft-versus-host disease when incubated with the donor's marrow¹¹. Anti-brain serum, however, does not lose its stem-cell toxicity after exhaustive absorption with T cells¹². Several other reports deal with antisera against haemopoietic or colony-forming stem cells. As a stem-cell label such antisera are, however, of little value because they usually react with species-specific antigens or H-2 alloantigens occurring on cells of various other organs.

Th-1.1 in rats is the first alloantigen restricted to stem cells and θ antigen-bearing cells. It is not only absent from B lymphocytes but, in contrast to mice, also from most peripheral T cells¹³. Again in contrast to mice where the concentration of Th-1.1 lymphocytes in the marrow is below 5%¹—Williams found 30–45% Th-1.1 positive cells in the rat bone marrow⁵. Considering the poor

immunocompetence of rat marrow Williams classifies Th-1.1 marrow cells as prothymic—having expressed their Th-1.1 molecule already in the bone marrow—rather than as mature post-thymic lymphocytes. Such a comparatively early expression of the Th-1.1 antigen in rat marrow may explain why Th-1.1, in the rat, can be detected also on haemopoietic stem cells. While this is speculative, the restrictive specificity of the Th-1.1 antigen, which is absent from myeloid cells and, in the rat, from over 90% of thoracic duct and lymph-node cells^{1,3}, should make it a useful marker of haemopoietic stem cells.

I thank Ms J. Molitor and B. Glöckner for technical assistance.

Catecholamine hormone receptors are reduced on chronic lymphocytic leukaemic lymphocytes

ADENYLATE cyclase (EC 4.6.1.1.) is a bifunctional enzyme that responds to biological signals such as hormones as well as catalysing the synthesis of cyclic 3',5'-AMP. Several reports indicate that the hormonal responsiveness of this enzyme in transformed or neoplastic cells is altered¹⁻³. This may explain the low cyclic AMP levels that have been associated with the unregulated cellular proliferation seen in transformed cells⁴⁻⁶. There is also evidence to implicate cyclic AMP in normal lymphocyte activation^{7,8}. Comparison of circulating lymphocytes from chronic lymphocytic leukaemia (CLL) patients with those from normal human controls indicates that cyclic AMP levels^{9,10}, cyclic nucleotide phosphodiesterase^{11,12} and adenylate cyclase¹³ activities are changed in the CLL lymphocyte. The membrane enzyme activity of 5' nucleotidase¹⁴ as well as complement¹⁵, antigen¹⁶ and lectin¹⁷ binding are also altered in the CLL plasma membrane. The observation that catecholamine hormone (β -adrenergic) responsiveness is depressed in CLL lymphocytes is further evidence for a functionally altered plasma membrane¹³. Until now, it has not been possible to identify the molecular lesion responsible for the reduced catecholamine sensitivity. But, with the availability¹⁸⁻²⁰ of radiolabelled molecules that bind efficiently and directly to specific β -adrenergic hormone receptor sites (for example (–)³H-dihydroalprenolol), we can now determine whether the CLL adenylate cyclase defect occurs in the β -adrenergic hormone-receptor complex, in the transducing mechanism that couples the receptor to the catalytic component, or in the intrinsic catalytic mechanism. We show here that the number of β -adrenergic hormone receptor sites is reduced on CLL lymphocyte membranes while the catalytic capacity of the cyclase enzyme is normal. The low density of catecholamine hormone receptors could account for the altered cyclic AMP metabolism and may

contribute to the unregulated growth of CLL lymphocytes.

Lymphocytes were isolated from heparinised blood from healthy human volunteers (100–400 ml) and from patients with chronic lymphocytic leukaemia (10–30 ml). The diagnosis of CLL was made after complete haematological evaluation including bone marrow biopsy. All steps in the isolation were done using sterile techniques. The lymphocytes were separated by centrifuging the blood on Ficoll-Hypaque density gradients using the method of Boyum²¹. Cells at the interphase were collected and diluted 1:1 with 199 medium plus 5% foetal calf serum, centrifuged at 450g for 10 min, and the resulting pellet was washed with 20 ml of the same medium. The washed cells were further purified immediately or resuspended in 40 ml 199 medium plus 10 ml calf serum, placed in a Falcon 75 cm² flask and stored in a 37 °C, 5% CO₂ humidified incubator (up to 10 h).

Subsequently, the non-adherent mononuclear cells were collected by centrifugation at 200g for 10 min. The cells were resuspended to a concentration of about 5×10^7 cells per ml and passed over nylon wool. Lymphocytes were collected by centrifugation (300g for 10 min) and washed twice (50 ml, 20 ml) with phosphate buffered saline pH 7.2 containing 0.1% gelatin. Greater than 90% of the cells were lymphocytes by microscopy. In selected experiments separation of B and T cells with recovery of both depleted and enriched fractions was performed as described by Kaplan *et al.*²². The final pellet was resuspended in 15 ml cold 50 mM Tris-HCl, 10 mM MgCl₂, pH 8.1 at 4 °C (incubation buffer), allowed to swell for 20 min, and homogenised by 25 up and down strokes in a pre-chilled (0 °C) Dounce homogeniser. The homogenate was centrifuged at 25,000g for 15 min, the pellet was rinsed once with cold incubation buffer (1 ml buffer per 5×10^7 cells). Adenylate cyclase activity of this membrane preparation was determined by the method of Brown²³. Protein was measured by the method of Lowry *et al.*²⁴.

The procedure for determining the density of hormone receptor sites on lymphocyte membranes was based on the method of Williams *et al.*²⁵. To tubes containing (–)³H-dihydroalprenolol (final concentration 1–80 nM) with and

Table 1 Adenylate cyclase activity of normal and CLL lymphocytes

Cell population	Adenylate cyclase activity (pmol per min per mg protein)		
	Basal	F [–] (10 mM)	Isoprenaline (10 μ M)
Normal lymphocytes	39	131	103
CLL lymphocytes	24	70	32

Adenylate cyclase activity was measured by analysis of the cyclic AMP²³ produced in a 10-min, 30 °C, incubation of the lymphocyte membranes in a buffer containing 40 mM Tris, 5 mM Mg²⁺, 5 μ g ml^{–1} R020-1724 (Hoffman-La Roche), 1 mM dithiothreitol, 2 mM ATP and additives at the concentrations indicated. The values are averages of duplicates from a representative experiment.

without (\pm)propranolol (10^{-3} M final concentration) was added 160 μ l of lymphocyte homogenate (40–130 μ g protein) to give a total volume of 200 μ l. Tubes were incubated for 13 min at 37 °C. Incubation was terminated by adding 4 ml of ice-cold incubation buffer to the tube and rapidly filtering contents through a Gelman-type A/E glass fibre filter under low vacuum. The filter was rinsed (ice-cold incubation buffer) with a 4 ml wash of the tube and a final (8 ml) rinse. Filters were placed in 10 ml of 10% BioSolv (Beckman), 90% toluene, 0.4% omnifluor, scintillation cocktail and allowed to stand overnight before counting.

In each experiment, 'nonspecific' binding was determined by parallel assay tubes which contained a large excess (10 μ M) of (\pm)propranolol. 'Specific' binding was defined

as the difference between the total and nonspecific binding.

The (–)³H-dihydroalprenolol was from New England Nuclear who prepared the radiolabelled product by catalytic reduction of (–)alprenolol using tritium gas with palladium as a catalyst. The molecular structure (determined by mass spectroscopy) is dihydroalprenolol and the tritium is probably found at the unsaturated bond in the aliphatic chain on position 2 of the aromatic ring.

The reactivity of the CLL lymphocyte adenylate cyclase to the β-adrenergic agonist, (–)isoprenaline (Sigma) is appreciably less than that of the enzyme prepared from normal lymphocytes (Table 1). However, fluoride stimulation of the CLL enzyme is comparable with that of normal controls (threefold stimulation). This response of the enzyme to fluoride indicates that the catalytic mechanism of the CLL enzyme is functioning properly.

Using (–)³H-dihydroalprenolol as a specific β-adrenergic ligand to bind directly and specifically to β-adrenergic hormone receptors, we compared crude membrane preparations from normal and CLL lymphocytes. Figure 1 illustrates the reduced binding of the radiolabelled ligand by CLL membranes. The normal cells showed considerable binding which corresponded to approximately 6,000 molecules bound per cell. Ligand binding to CLL membranes was too low to assess accurately, but it was less than 2,000 molecules per cell. The control dose-response curve exhibits saturation at 6×10^{-8} M, indicating an approximate K_d of 3×10^{-8} M for the dihydroalprenolol. Both control and CLL binding reactions showed about 70% specific binding of the (–)³H-dihydroalprenolol in the experimental conditions. In addition to the saturability and high affinity, the specificity of the dihydroalprenolol binding was indicated by its stereospecificity (1-stereoisomers of isoprenaline and propranolol were more efficient in displacing the bound (–)³H-dihydroalprenolol than the *d*-stereoisomers) and the binding

showed rapid kinetics for association reaching a steady-state within two minutes. Furthermore, the displacement of (–)³H-dihydroalprenolol by 10^{-6} M propranolol was approximately the same as 10^{-4} M isoprenaline which is consistent with the potency of these agents on other well characterised β-adrenergic receptors.

All of the CLL patients in this study had increased percentages of lymphocytes with monoclonal surface immunoglobulin (Ig) suggesting that the disease probably represents a proliferation of B lymphocytes¹⁶. To exclude the possibility that the depressed (–)³H-dihydroalprenolol binding was not simply a characteristic of cells with surface Ig, separation of normal lymphocytes into T and B populations was performed. Table 2 shows, in fact, that membranes isolated

Table 2 (–)³H-Dihydroalprenolol bound to human lymphocytes

Cell population	(–) ³ H-dihydroalprenolol bound† (fmol per mg membrane protein)
Normal lymphocytes (8)*	682 ± 114
'T' lymphocytes, normal (2)	532 ± 132
'B' lymphocytes, normal (2)	1,439 ± 83
CLL lymphocytes (10)	220 ± 69

Lymphocyte preparation and separation into 'B' and 'T' subpopulations were performed as described in the text. Of the cells in the 'B' fraction, 61% have surface immunoglobulin, while 89% of the 'T' rich portion formed red blood rosettes²². Binding was measured²⁵ at a concentration of 5×10^{-8} M (–)³H-dihydroalprenolol. The averages of triplicate determinations were done for each experiment and the averages used to determine the standard error of the differences between the normal and CLL lymphocytes. Normal and CLL values showed a significant statistical difference which is represented by $P < 0.001$.

*Value in parentheses is number of separate experiments.

† Mean ± s.e.m.

from non-T cells (surface Ig positive) bind more (–)³H-dihydroalprenolol than those isolated from T lymphocytes. This indicates that enrichment of B cells in the CLL lymphocyte population could not account for the observed hormone receptor differences between normal and CLL cells.

CLL lymphocyte adenylate cyclase is β-adrenergic unresponsive, although the homogenates exhibit fluoride-stimulated adenylate cyclase activity, showing that the catalytic component of the enzyme is behaving normally. We have shown that the density of the β-adrenergic hormone receptor site is decreased in CLL lymphocytes. This alteration in the number of β-adrenergic hormone receptor sites could explain the loss of CLL β-adrenergic adenylate cyclase responsiveness observed first by Polgar *et al.*¹³. It may also account for the depressed cellular levels of cyclic AMP found in CLL lymphocytes⁹. Depressed cyclic AMP levels are known to be correlated with unregulated cellular growth⁴, a characteristic of the neoplastic state.

A decreased capacity of cultured transformed cells to bind radiolabelled hormones has been recently observed. Differences in polypeptide hormone receptor sites^{26,27} as well as the catecholamine hormone receptors²⁸ were found in comparisons of virus-transformed cells with normal, growth regulated cells. Previous studies of 5' nucleotidase¹⁴ complement¹⁵ antigens¹⁶ and plant lectins¹⁷ have all indicated that the membrane of the CLL cells is structurally and functionally aberrant. Our observations show that the density of β-adrenergic hormone receptor sites is decreased on the CLL lymphocyte surface. Membrane alterations such as these that interfere with basic mechanisms of biological communication may be fundamental to the aetiology of diseases characterised by unregulated cellular proliferation.

We thank Elizabeth Anton for technical assistance. The separation of lymphocyte subpopulations was performed in the laboratory of Dr M. Kaplan. This research was supported by grants from the USPHS, the Veterans'

Fig. 1 (–)³H-dihydroalprenolol binding, as a function of concentration, was measured for lymphocyte membranes prepared as described in the text. This figure shows a single representative experiment with the range bars enclosing the area of all the experiments performed (12 normal and 10 CLL lymphocyte preparations). ○, Normal lymphocytes; ●, CLL lymphocytes.

Actin co-caps with concanavalin A receptors

PREVIOUS studies have given mainly indirect^{1,2}, and some direct^{3,4} evidence that the mobility of surface membrane receptors may be controlled by cytoplasmic microfilaments and microtubules. It has been proposed^{1,2} that the receptor-cytoskeletal complex may have important roles in cell-cell recognition, cell motility and cell division. This study, using two fluorochromes to identify concanavalin A (con A) receptors and cytoplasmic actin in the same cell, shows that con A binding to neoplastic and embryonic cell surfaces results in dissolution of actin filaments and that con A receptors and actin co-cap and occur in closely related sites in untreated and cytochalasin B-treated cells.

Monolayer cultures of rat fibroblasts were prepared from normal adult kidney, dimethylnitrosamine (DMN)-induced renal mesenchymal tumours⁵, transformed kidney cell lines derived from DMN-treated rats⁶, 15-20 d foetal kidney or lung⁷ and 5-10 d whole embryos. The cells were tested either untreated, or after exposure for 20-60 min to 2×10^{-5} M cytochalasin B, 10^{-2} to 10^{-6} M colchicine, 10^{-5} M vinblastine, 2×10^{-3} M procaine or $10 \mu\text{g ml}^{-1}$ trypsin.

Marginal and/or random surface staining was seen in adult, tumour, transformed, embryonic and foetal fibroblasts incubated with fluorescein-isothiocyanate (FITC)-labelled con A at 4 °C, and in adult and foetal fibroblasts incubated at 37 °C (Fig. 1a, Table 1). In contrast, tumour, transformed and embryonic fibroblasts, incubated with FITC-con A at 37 °C for 20 min, showed staining in fine clusters (Fig. 2a), and at the cell margins and processes. Incubation of these cells for increasing time periods

Fig. 1 FITC-con A followed by AAA/R-AHG staining of cultured adult kidney fibroblasts. Con A receptors were demonstrated by immunofluorescence reactivity¹⁵ of cell surfaces with FITC-labelled con A. Cytoplasmic actin was detected by AAA traced with R-AHG. The fluorescein: protein molar ratio and protein content of the conjugates were 4.9 and $300 \mu\text{g ml}^{-1}$ for FITC-con A, and 3.3 and 4 mg ml^{-1} for R-AHG. Tests were done at 4 °C or at 4 °C warmed to 37 °C for 20-360 min. Specificity of the FITC-con A staining was established by inhibition with unlabelled con A ($1,000 \mu\text{g ml}^{-1}$) or with 0.1 M α -methyl-D-mannopyranoside. The AAA specificity was established by immunoabsorption with muscle actin⁸. a, Adult kidney fibroblast, sub-1 stained with FITC-con A showing linear staining of the cell periphery ($\times 330$). b, Same cell as in (a) stained with AAA/R-AHG showing parallel actin filaments located in closely related sites as those seen in (a) ($\times 330$). c, Adult kidney fibroblast, sub-1, treated with cytochalasin B at 37 °C for 20 min and stained with FITC-con A at 37 °C for 20 min showing coarse clusters in the cell periphery. ($\times 330$). d, Same cell as in (c) stained with AAA/R-AHG showing coarse clusters in sites closely related to those seen in (c). ($\times 330$).

produced fine to coarse clusters in a central mass with clearing of the cell periphery at 40 min, a supranuclear cap of clusters at 60 min (Fig. 2c) and perinuclear globules at 120 min persisting until 360 min. Cells pretreated with 1% or 4% paraformaldehyde at 4 °C or 37 °C for 10 min showed staining restricted to cell margins both at 4 °C and 37 °C.

After 20-40 min of cytochalasin B (BL) treatment, adult and foetal fibroblasts tested with FITC-con A at 37 °C, showed fine clusters in cells with preserved cell shape and in contracted cells with cytoplasmic arborisations. After treatment for 40-60 min, the cells showed coarse, peripheral clusters in incompletely (Fig. 1c) or completely rounded up cells; supranuclear caps and perinuclear globules were not seen. Procaine treatment also produced fine to coarse clusters but colchicine and vinblastine did not alter the marginal and/or random surface staining seen in untreated cells. Trypsin induced a staining pattern of fine clusters. The cytoskeletal-disrupting drugs did not cause any changes in the initial staining pattern of fine clusters seen in tumour, transformed and embryonic cells (Table 1) but, with increasing incubation times, supranuclear caps and perinuclear globules were not seen.

Anti-actin antibody (AAA) (ref. 8) staining, traced with a rhodamine-labelled goat anti-human (γ) globulin (R-AHG), showed long parallel bundles of thick filaments in adult, embryonic and foetal fibroblasts (Fig. 1b) and short thin filaments with occasional fine aggregates in tumour and transformed cells⁹. Previous incubation of tumour, transformed, embryonic or foetal cells with FITC-labelled or unlabelled con A for 20 min and subsequent testing with AAA showed staining of fine aggregates, diffuse staining or no staining (Fig. 2b). The changes in staining patterns were most marked in neoplastic cells (> 90% cells), moderate in embryonic cells (70-90%) and minimal in foetal cells (< 10%). The change was more pronounced at 4 °C than at 37 °C. It was not seen in adult fibroblasts or in cells pre-treated with

Table 1 Immunofluorescence staining of monolayer cultures of adult, neoplastic, embryonic and foetal fibroblasts by FITC-con A or AAA

Experimental conditions	Adult, foetal kidney or lung fibroblasts		Tumour, transformed or whole embryo fibroblasts	
	FITC-con A	AAA	FITC-con A	AAA*
4 °C	Cell margins	Filaments	Cell margins and random	Filaments and fine aggregates
37 °C	Cell margins	Filaments	Fine clusters, supranuclear caps or perinuclear globules	Filaments and fine aggregates
Cytochalasin B†	Fine or coarse clusters	Fine or coarse aggregates	Fine clusters	Fine or coarse aggregates
Procaine	Fine or coarse clusters	Fine or coarse aggregates	Fine clusters	Fine or coarse aggregates
Colchicine or vinblastine	Cell margins	Filaments	Fine clusters	Filaments and fine aggregates
Trypsin	Fine clusters	Fine aggregates, diffuse or negative	Fine clusters	Fine aggregates, diffuse or negative

Viable monolayer cultures were treated for 20–360 min with $300 \mu\text{g ml}^{-1}$ FITC-con A in tissue culture medium 199. Drug-treated cells were pre-incubated with the reagent for 20–60 min followed by a further period of incubation, with or without the reagent, with FITC-con A for 20–120 min. AAA staining was carried out with cultures, fixed by air-drying and leaving at 4 °C for 2 h. Staining was still detectable with $20 \mu\text{g ml}^{-1}$ FITC-con A or 1:256 dilution AAA. The staining patterns were present in > 90% of cultured cells.

*Previous treatment of viable cultures with FITC-labelled or unlabelled con A resulted in dissolution of actin filaments.

†Treatment of control cultures with the cytochalasin B solvent, dimethylsulphoxide, had no effect on FITC-con A or AAA staining patterns.

FITC-labelled AHG at 4 °C or 37 °C, or pre-cooled at 4 °C for 10 min and tested at 4 °C with AAA.

Our data show that con A receptors may be structurally linked to actin since the two components occur in closely related sites in all the cell types examined (Figs 1, 2). This link may take the form of an actin sub-set, not stained by AAA, which restricts con A receptor mobility in adult and mature foetal cells and which is poorly expressed in neoplastic and embryonic cells. The suggestion is

supported by our finding that cluster formation may occur in cells containing actin filaments (Fig. 2a, b) and can be induced in adult or foetal cells by cytochalasin B treatment. The proposal is also consistent with the observed decrease in membrane-associated actin in tumour cells¹⁰. Because the linear marginal distribution of con A receptors is in close proximity to actin filaments (Fig. 1a, b) we suggest that the actin sub-set may anchor con A receptors to actin filaments. An actin sub-set is also thought to limit con A receptor mobility in normal alveolar macrophages¹¹. Lattice microfilaments¹² are a possible candidate for this actin sub-set.

Con A binding to surface receptors result in conversion of filamentous actin to aggregates or a diffusely stained form. These latter forms of actin seem essential for capping and endocytosis since FITC-con A and AAA-stained areas occur in close proximity (Fig. 2c, d) and the processes are inhibited by CB. Microtubules may also have a role in capping and endocytosis as these processes are inhibited by colchicine or vinblastine. Inhibition of capping by cytochalasin B, vinblastine, colchicine or procaine supports the results of previous workers^{13,14}. The cytochalasin B-induced 'caps' reported in a recent study³ may not represent true caps but may result from cytochalasin B-induced disruption of actin filaments.

Actin and tubulin co-cap with surface immunoglobulins in mouse B lymphocytes

CYTOSKELETAL control of cell surface receptor movements¹ has been suggested by several authors^{2,3} and is compatible with the fluid mosaic model of cell membranes⁴. Evidence for this hypothesis comes mostly from experiments using drugs which alter the activity of cytoskeletal components^{5,6}. We report here co-capping of actin and tubulin with immunoglobulins (Ig) in B lymphocytes from mouse spleen. These findings provide structural evidence for cytoskeletal control of receptors.

Purified anti-actin and anti-tubulin antibodies were obtained respectively from the serum from a patient with chronic aggressive hepatitis, which contained specific anti-actin antibodies^{7,8} and from the sera of rabbits repeatedly immunised with pig brain tubulin⁹ adsorbed to alum (A.Z. and G.G., in preparation). These sera were passed through columns of Sepharose covalently linked¹⁰ respectively with rabbit skeletal muscle actin¹¹ or with pig brain tubulin¹⁴, and the absorbed antibody was eluted at pH 2.7. The specificity of these antibodies was shown by immunodiffusion—a single precipitation line was observed against the antigen (Fig. 1)—by immunoelectrophoresis, and by immunofluorescence. In the immunofluorescence test the anti-actin antibody (AAA) was fixed on striated (I bands) and smooth muscle tissue sections and the anti-tubulin antibody (ATA) on mitotic spindles, cultivated fibroblasts and spermatozoa; cell staining was abolished by previous incubation of the antibody solution with actin and tubulin respectively.

Mouse spleen lymphocytes were incubated with rabbit antiserum against mouse Ig (RAMIG), either conjugated with rhodamine¹² or unconjugated, and then with sheep antiserum against rabbit Ig (SARIG) conjugated with rhodamine¹²; conditions were as described elsewhere¹³ and incubations were for 30 min at 0 or 37 °C. After this incubation the cells were suspended in 0.035 M citrate¹⁴, a drop of this suspension was applied on a slide and dried. For actin staining, cells

Fig. 1 Immunodiffusion experiments using the Ouchterlony technique. Readings were made between 24 and 48 h after a single filling of the wells. *a*, AAA serum was placed in the centre against decreasing concentrations of actin (3.0; 1.5; 0.75; 0.375; 0.19 mg ml⁻¹). To keep actin depolymerised, Agarose (Behring-Werke) was dissolved in 2 mM Tris-HCl buffer at pH 8.0 containing 0.2 mM ATP, 0.5 mM 2-mercaptoethanol and 0.2 mM CaCl₂ (ref. 10). *b*, ATA serum was placed in the centre against similarly decreasing concentrations of tubulin. Agarose was dissolved in 0.15 M NaCl containing 0.5 mM 2-mercaptoethanol. A single precipitation line is visible in both cases.

Fig. 2 Immunofluorescent staining of splenic B lymphocytes incubated in suspension with RAMIG and SARIG-rhodamine, then fixed with ethanol and incubated with AAA followed by anti-human IgG-fluorescein. All photographs were taken with a Zeiss ultraviolet photomicroscope equipped with epi-illumination and specific filters for rhodamine and fluorescein, using a Plan Apo-Chromate 63x/1.0 objective on HP5 Ilford black and white film. *a-c*, Incubation in suspension at 4 °C; *a*, rhodamine; *b*, fluorescein; *c*, phase contrast. *d-f*, Incubation in suspension at 37 °C; *d*, rhodamine; *e*, fluorescein; *f*, phase contrast. *g-i*, Incubation in suspension at 37 °C; as control, after ethanol fixation cells were incubated with human Ig instead of AAA and then with anti-human IgG. *g*, Rhodamine; *h*, fluorescein; *i*, phase contrast ($\times 2,000$).

were fixed for 30 s in absolute ethanol, incubated for 15 min with purified AAA and for a further 15 min with fluorescein conjugated Ig fraction of goat antiserum to human IgG (Miles Seravac). To avoid cross reactions between these antisera, the goat anti-Ig was passed on a solid immunoabsorbent made with glutaraldehyde-coupled mouse, rabbit and sheep Ig¹⁵. In control experiments the human purified AAA was replaced by a solution of normal human Ig with a similar concentration of proteins. For tubulin staining, cells incubated with RAMIG-rhodamine were fixed for 20 min in 3.7% formaldehyde and 5 min in acetone, and then incubated for 1 h with a solution of fluorescein conjugated¹² rabbit purified ATA.

After incubation in suspension with RAMIG-rhodamine or RAMIG followed by SARIG-rhodamine, 70% of splenic lymphocytes had a positive staining. Cells incubated at 0 °C had a generally diffused labelling along the cell membrane with some patching and very rare capping, whereas a high proportion of cells incubated at 37 °C showed typical cap formation. When this incubation was followed by fixation of the cells and immunofluorescent staining for cytoskeletal proteins, the pattern of actin and tubulin corresponded to that of Ig (Figs 2 and 3). In non-capped cells, the fluorescence was weak, particularly for actin, and difficult to detect on the nuclear area. By contrast, in cells showing capped immunoglobulins,

Fig. 3 Immunofluorescent staining of splenic B lymphocytes incubated in suspension with RAMIG-rhodamine then fixed with formaldehyde and acetone and incubated with ATA-fluorescein. *a-c*, Incubation in suspension at 4 °C; *a*, rhodamine; *b*, fluorescein; *c*, phase contrast. *d-f*, Incubation in suspension at 37 °C; *d*, rhodamine; *e*, fluorescein; *f*, phase contrast ($\times 2,000$).

the fluorescence for actin and tubulin was intense and restricted to the region of the cap. Among the cells which were rhodamine negative (that is, non-B cells) a high proportion (85%) were positive for actin and tubulin.

These findings show in a simple and well established model¹ that two cytoskeletal proteins, namely actin and tubulin, probably having different functions, move concurrently along the cell membrane with a single class of surface receptors—Ig. It has been reported that, in rabbit ovarian granulosa cells, concanavalin A-induced capping redistributes microtubules in the cytoplasmic region underlying the cap¹⁶. An analogous redistribution of surface antigens and actin has been described in Lu-106 cells after treatment with cytochalasin B¹⁷.

It is generally recognised that capping is dependent on cell metabolism^{1,18}. Several experiments have shown that cytochalasin B (a drug which alters microfilament morphology and function¹⁹) inhibits this phenomenon (though sometimes only partially)^{5,20} and hence it has been proposed that redistribution of cell surface molecules depends on microfilament activity. Microtubular integrity has also been shown to be linked with capping in B lymphocytes²¹. It has been proposed that microtubules and microfilaments exert skeletal and contractile actions respectively in regulating the movement of cell surface proteins³. Our findings are compatible with this hypothesis, and support the possibility that skeletal and contractile elements are linked to one another and/or to the same plasma membrane components.

Intracellular binding sites for insulin are immunologically distinct from those on the plasma membrane

SPECIFIC high affinity binding sites for insulin have been shown to be located on the plasma membrane of target cells¹, and they are also present on purified intracellular organelles² including intact nuclei³, smooth and rough endoplasmic reticulum^{2,4}, and the Golgi apparatus⁵. Although these intracellular sites have certain binding characteristics similar to those on the plasma membrane²⁻⁵, it is not known whether these binding sites share other biochemical features. Using an antiserum directed at the cell surface binding sites, we have found that several types of intracellular binding sites for insulin are immunologically distinct from those on the plasma membrane.

It has already been demonstrated that the sera of certain patients with extreme insulin resistance and acanthosis nigricans contain immunoglobulins directed against the plasma membrane binding site⁶⁻⁹. When any of human monocytes or cultured lymphocytes, avian erythrocytes, or highly purified rat liver plasma membranes are preincubated with these antisera, the subsequent binding of radiolabelled insulin is inhibited⁶⁻⁹. That these antibodies are specific for insulin binding sites on the plasma membrane is seen by their failure to inhibit both the binding of human growth hormone to intact human cultured lymphocytes⁶⁻⁹ and the binding of NSILA-s, an insulin-like peptide, to rat liver plasma membranes⁶⁻⁹. Furthermore, using conditions where there is nearly complete inhibition of the specific binding of insulin, there is no inhibition of the binding of glucagon (Table 1). Other studies indicate that the binding of purified radiolabelled antibodies to plasma membranes is inhibited by insulin and insulin analogues in direct proportion to the biological activity of those analogues⁶⁻⁹. These findings suggest that these antibodies bind either near to or at the portion of the plasma membrane that recognises and binds the insulin molecule.

When we pre-incubated rat liver plasma membranes with B2-1975 antiserum⁶⁻⁹ at a 1:100 dilution for 1 h at 4 °C, 85-90% of the subsequent binding of ¹²⁵I-insulin was inhibited (Table 1, Fig. 1). With progressive serial dilution, the inhibiting effect decreased; but even at a titre of 1:6,400, 25% inhibition of binding was demonstrable. In contrast to its ability to inhibit insulin binding to the plasma membrane, this antiserum had no significant effects on the binding of insulin to purified nuclei (Table 2). We have previously shown that the nuclear membrane is the major site of insulin binding to the cell nucleus¹². In contrast to the marked inhibition of the binding of insulin to plasma membranes, pre-incubation of nuclear membranes with B2-1975 antiserum had only small effects on insulin binding (Table 2, Fig. 1). Similar results were seen with the smooth endoplasmic reticulum (Table 2, Fig. 1). At a dilution of 1:100, specific binding of insulin to both nuclear membranes and smooth endoplasmic reticulum was inhibited by only 10-20%;

Fig. 1 Effects of serial dilutions of an anti-plasma membrane antiserum on ^{125}I -insulin binding to several types of cellular membranes. Plasma membranes¹⁰ (●) at 0.087 mg protein ml^{-1} (a) and 0.125 mg protein ml^{-1} (b), nuclear membranes¹³ (○) at 0.087 mg protein ml^{-1} , and smooth (Δ) and rough (▲) endoplasmic reticulum¹⁴ at 0.47 mg protein ml^{-1} were pre-incubated for 1 h with either normal human serum or antiserum at various dilutions as described in Table 1. ^{125}I -Insulin (0.5 ng ml^{-1}) and albumin (5 mg ml^{-1}) were then added and the incubation was continued for 2 h. Insulin bound to nuclear and plasma membranes was separated from free insulin by centrifugation in a microcentrifuge. Insulin bound to the rough and smooth endoplasmic reticulum was separated by a filtration through Oxoid filters (Amersham)^{3,11}. Each point is the mean of triplicate determinations. Binding is expressed as a percentage of that seen in the presence of pooled human serum. In the absence of antiserum specifically bound ^{125}I -insulin (% of total) was 3.95 ± 0.07 (a) and 5.75 ± 0.14 (b) for plasma membranes, 0.85 ± 0.008 for nuclear membranes, 3.4 ± 0.14 for smooth endoplasmic reticulum, and 1.9 ± 0.04 for rough endoplasmic reticulum. Values are the mean \pm standard deviation.

the degree of inhibition, moreover, did not change with dilution of the antiserum up to 1:3,200.

The ability of this antibody to inhibit insulin binding to the rough endoplasmic reticulum was also much less than that seen with plasma membranes (Table 2, Fig. 1). At a dilution of 1:100, approximately one-third of the specific binding of insulin was inhibited. In contrast to the results obtained with smooth endoplasmic reticulum and nuclear membranes, the inhibition of insulin binding to the rough endoplasmic reticulum progressively diminished on further dilution of the antiserum.

There are two possible reasons why this antiserum partially inhibits insulin binding to intracellular membranes. In the case of the rough endoplasmic reticulum, it is possible that the inhibition observed represents the interaction of the antibody to plasma membrane insulin binding sites with nascent plasma membrane binding sites present on ribosomes. Since this antiserum (B2-1975) also contains antibodies directed against a variety of cell proteins⁹, it is possible that the non-progressive inhibition observed with nuclear membranes or smooth endoplasmic reticulum is caused by a second antibody present in the antiserum that only weakly inhibits binding. In either case, the present studies suggest that the insulin binding sites on these intracellular membranes from rat liver are

Table 1 Effect of an anti-plasma membrane antiserum on the binding of ^{125}I -insulin and ^{125}I -glucagon to rat liver plasma membranes

	^{125}I -hormone bound (% per 0.1 mg protein per ml)	
	Insulin	Glucagon
Control serum	4.0 ± 0.21	10.2 ± 0.13
Antiserum	0.5 ± 0.12	9.9 ± 0.40

Rat liver plasma membranes¹⁰ at 0.057 mg protein ml^{-1} were preincubated for 1 h at 4 °C with a 1:100 dilution of antiserum (B2-1975) (refs 6-9) or control serum in buffer containing 0.25 M sucrose, 10 mM MgCl_2 , 2 mM EDTA, 20 mM Tris (pH 7.85). After this pre-incubation, either ^{125}I -insulin³ at 0.75 ng ml^{-1} in the presence or absence of 200 $\mu\text{g ml}^{-1}$ of unlabelled insulin (to determine nonspecific binding) or ^{125}I -glucagon¹¹ at 0.5 ng ml^{-1} in the presence or absence of 50 $\mu\text{g ml}^{-1}$ of unlabelled glucagon was added with bovine serum albumin at 5 mg ml^{-1} . The incubation was continued at 24 °C for 2 h for insulin or 1 h for glucagon. Bound and free hormones were separated by centrifugation in a microcentrifuge^{3,11}. Each value is the mean \pm the standard deviation for triplicate determinations. Nonspecific binding has been subtracted.

immunologically distinct from those found on the plasma membrane.

It is evident that, per unit of protein, plasma membranes bind more insulin than do the intracellular membranes (Table 2). Our preliminary studies suggest that this increased binding of insulin to plasma membranes is due to the higher affinity of its insulin binding sites. In contrast, the total number of insulin binding sites per unit of protein (binding capacity), is similar in the various cellular membrane fractions. Since it is well known that the liver cell has far more intracellular membranes than plasma membranes, this observation suggests that there may be more binding sites for insulin in the cell interior than there are on the cell surface.

The biological significance of these intracellular binding sites for insulin is unknown. It has been postulated that certain of these intracellular binding sites, especially those on Golgi membranes, are precursors of those on plasma membranes⁸; this argument may also pertain to those sites on the rough endoplasmic reticulum. Conversely since it is unlikely that the insulin binding sites on the nuclear membrane and on the smooth endoplasmic reticulum are precursors of those on the plasma membrane, and since the present studies indicate that these intracellular binding sites for insulin are immunologically distinct from those on the plasma membrane, an alternative hypothesis can be made. We and others have either deduced or observed that both insulin and other polypeptide hormones may enter the intact cell¹⁵⁻²⁰. On the basis of these data, we have speculated that these intracellular binding sites for insulin may be involved in the regulation of several long term effects of insulin, such as RNA and DNA synthesis^{15,16}. Since the

Table 2 Effect of an anti-plasma membrane antiserum on ^{125}I -insulin binding to various cellular fractions

Fraction	^{125}I -insulin bound (% of total)		Inhibition of binding (%)
	No antiserum	Antiserum 1:200	
Plasma membranes (0.035)	1.14 ± 0.02	0.16 ± 0.006	86
Nuclei (1.03)	1.34 ± 0.15	1.36 ± 0.16	0
Nuclear membranes (0.12)	1.04 ± 0.01	0.86 ± 0.02	17
Smooth ER (0.23)	1.70 ± 0.08	1.50 ± 0.10	12
Rough ER (0.47)	1.91 ± 0.04	1.32 ± 0.04	31

For each fraction the protein concentration (shown in parentheses as mg ml^{-1}) was adjusted so that 1-2% of the ^{125}I -insulin was specifically bound. Incubation conditions were as described in Table 1 and Fig. 1. Binding is expressed as the mean \pm standard deviation for triplicate determinations. Inhibition of insulin binding by the antiserum was significant in all fractions ($P < 0.05$) except nuclei.

relationship between the intracellular binding sites for insulin and the biological functions of insulin is unknown, further studies will be necessary to clarify the role, if any, of these intracellular binding sites.

We thank Drs Marvin D. Siperstein and Basil Rapoport for advice on this manuscript. Inhibition of high-affinity choline transport in peripheral cholinergic endings by presynaptic snake venom neurotoxins

Use of purified snake venom neurotoxins with potent curarimimetic action on peripheral cholinergic transmission (for example, α -bungarotoxin¹) in the study of the biochemical properties of the nicotinic cholinergic receptor has met with considerable success (see ref. 2 for review). Some of the crude venoms from which such toxins have been isolated also contain toxins which act presynaptically, such as β -bungarotoxin¹, notexin³ and taipoxin⁴. These three toxins inhibit the release of acetylcholine by a mechanism which is independent of the release process *per se*³⁻⁷. We show here that in an *in vitro* membrane preparation⁸ derived from the cholinergic endings in *Torpedo* electric organ these and related toxins are potent inhibitors of the high-affinity choline transport system. These observations provide a biochemical explanation for the inhibitory action of these toxins on transmitter release as they effectively block re-synthesis of acetylcholine from choline.

Nerve terminal sacs (T sacs, originally termed synaptosomes⁸) were prepared from the electric tissue of *Torpedo marmorata* essentially as described previously⁸ (for a detailed account see

ref. 9). After a brief period of pre-homogenisation of this tough tissue in 0.8 M glycine using a Waring blender, homogenisation in a Potter-Elvehjem glass and Perspex homogeniser was possible. Uptake of ³H-choline into partially purified T sacs (fraction *P*₂) was measured using a Millipore filtration technique as described recently¹⁰. The effects of the various toxins and related proteins on choline uptake were tested in several ways. The concentration dependency of their inhibitory action was tested by simultaneous exposure of T sacs to ³H-choline (1 μ M) and toxins (varying concentrations) for 10-15 min before filtration. In other experiments T sacs were exposed to toxins before the addition of ³H-choline, and vice versa. In experiments designed to test the calcium dependence of the toxin action the 4.4 mM CaCl₂ of the normal *Torpedo* Ringer (for composition see ref. 10) was replaced by 4.4 mM SrCl₂.

Figure 1 shows that all three toxins (β -bungarotoxin, notexin, and taipoxin) that are known to have presynaptic effects are potent inhibitors of high-affinity choline transport. By contrast those with a postsynaptic action (α -bungarotoxin and *siamensis* 3)¹⁸ in the same concentration range were without effect (data not shown). Two other toxins (*Notechis* II-5 and *Enhydryna schistosoma* myotoxin) which are structurally homologous to notexin and the taipoxin subunits^{7,11-13} are also very potent inhibitors. Experiments in which T sacs were exposed to taipoxin or β -bungarotoxin for 10-15 min at room temperature before the addition of ³H-choline show that this potentiates the inhibitory action of taipoxin 10-fold whereas that of β -bungarotoxin is not significantly altered. The increased potency of taipoxin is not due to increased binding of the toxin to the T-sac membrane but rather to a potentiating factor released from the tissue during incubation (M.J.D. and J.P.F., in preparation).

The shapes of the inhibition curves suggested that all of the inhibitory toxins except β -bungarotoxin were capable of producing full blockade. For notexin and *Notechis* II-5 it was not possible to demonstrate complete inhibition because of the increased nonspecific binding of ³H-choline to the Millipore filters at high toxin concentrations. In contrast to the retention of ³H-choline at lower toxin concentrations this binding was insensitive to the presence of hemicholinium-3 and thus probably represents a strong interaction between ³H-choline and filter-bound toxin. With β -bungarotoxin, inhibition was never more than 60% even at concentrations above 30 μ g ml⁻¹. In the presence of 100 and 200 μ g ml⁻¹ β -bungarotoxin nonspecific binding of ³H-choline to the filters was also observed and this obscured the real inhibition pattern of this toxin at these elevated concentrations. By extrapolation this effect was not sufficient to explain the partial blockade caused by β -bungarotoxin, however. The most potent uptake-blocker, notexin, had an IC₅₀ value (concentration for 50% inhibition) of about 4×10^{-11} M. In cases where comparison is possible (β -bungarotoxin, notexin and taipoxin) the range of concentrations in which inhibition was observed is similar to or lower than that previously reported for *in vitro* presynaptic inhibition based on physiological findings^{1,3,4,7}. The latency of the presynaptic toxins *in vivo* is well established. If the failure of transmission is due to termination of acetylcholine synthesis caused by inhibition of choline uptake one would not expect transmission to cease until the pre-existing pool of acetylcholine was exhausted. Comparisons of IC₅₀ values for choline transport in T sacs with the LD₅₀ values observed on intravenous administration to mice shows a high degree of correlation—particularly for the single-chain neurotoxins. The multiple-chain toxins, β -bungarotoxin and taipoxin, are more toxic to whole animals than might be predicted from their effects on choline transport.

All of the presynaptically-active neurotoxins shown in Fig. 1 are Ca²⁺-dependent phospholipases, and all of those which have been totally^{11,12} or partially^{7,13} sequenced are highly homologous to phospholipases A₂ from other snake venoms and from mammalian pancreas. We have therefore tested (Table 1) whether calcium is required for their inhibitory action on choline transport by performing some experiments in

Fig. 1 Inhibitory action of presynaptic snake neurotoxins on high-affinity choline transport. ^3H -choline uptake into partially purified T sacs (fraction P_2) from *Torpedo* electric organ was measured for 10–15 min at room temperature with 1 μM choline exactly as described previously¹⁰. The effect of increasing concentration of the various toxins added at the onset of incubation with ^3H -choline is expressed as % inhibition of controls to which no toxin was added. Each point represents the mean of two or more independent experiments with duplicate or triplicate determinations in each case. Replication of individual points was good both within or between experiments. For any one point the standard deviation from the mean was $< 10\%$ for $n = (4-13)$ observations. The identities of the various toxins, assumed molecular weights (MW) and references to the details of their purification are as follows: \blacktriangledown , notexin¹¹, MW 13,500; \bullet , *Notechis* II-5¹², MW 13,500; \triangle , *Enhydryna schistosa* myotoxin¹³, MW 13,500; \circ , taipoxin⁷, MW 45,600; \square , β -bungarotoxin (a gift from Boehringer prepared as in ref. 17), MW 22,000. Toxin concentrations causing 50% inhibition in ng ml^{-1} were: notexin, 0.5 (3.7×10^{-11} M) (2 expts); *Notechis* II-5, 9 (6.7×10^{-10} M) (2 expts); *En. schistosa* myotoxin, 36 (2.7×10^{-9} M) (2 expts); taipoxin, 310 (6.8×10^{-9} M) (4 expts); β -bungarotoxin, 5,600 (2.5×10^{-7} M) or for 50% of maximum inhibition, 630 (2.8×10^{-8} M) (5 expts).

Ca^{2+} -free Sr^{2+} -*Torpedo* Ringer. Although substitution of Ca^{2+} by Sr^{2+} has little effect on choline transport in the absence of the toxins none of the toxins exhibited either inhibitory activity or phospholipase A activity in the Sr^{2+} medium, which suggests that the integrity of the catalytic site is required for the toxic action.

Experiments of the type shown in Fig. 2 indicate that these toxins do not cause gross lysis of the presynaptic nerve-terminal membrane in the conditions used. Furthermore, the influx of ^3H -choline is immediately and totally inhibited by the addition of taipoxin, but continued incubation does not lead to loss of ^3H -choline. In the same conditions, 80% of the

Table 1 Ca-dependence of toxin action on choline uptake

Toxin ($\mu\text{g ml}^{-1}$)	Choline uptake at 1 μM (% of controls)	
	Sr^{2+} -Ringer	Ca^{2+} -Ringer
Notexin (0.01)	91 \pm 37	23 \pm 6
<i>Notechis</i> II-5 (0.1)	111 \pm 9	23 \pm 3
<i>E. schistosa</i> myotoxin (0.2)	127 \pm 3	33 \pm 4
Taipoxin (3)	89 \pm 15	9 \pm 2
β -bungarotoxin (10)	111 \pm 12	45 \pm 6

Fraction P_2 was prepared from *Torpedo* electric organ and resuspended in 'normal' *Torpedo*-Ringer (Ca^{2+} -Ringer) or one in which CaCl_2 was replaced by SrCl_2 with a final concentration of 4.4 mM (Sr^{2+} -Ringer). ^3H -choline uptake (10 min) was then measured (20 μg protein per assay) in the presence and absence of toxins in both Ringer solutions as described in the legend to Fig. 1. Toxin concentrations were chosen so as to produce about 80% of their maximum inhibition (see Fig. 1). Results are expressed as % of the appropriate controls and are means \pm s.d. of three individual determinations. The Sr -Ringer control was 93% of the Ca -Ringer control.

choline taken up remains as free choline in the cytosol¹⁴ and is readily released by agents which rupture the external membrane (see effect of crude bee venom phospholipase A in Fig. 2).

β -Bungarotoxin behaves like taipoxin except that the blockade is only about 50%, as mentioned above (Fig. 1). Another reason for rejecting gross lysis as an explanation for the inhibitory action of these toxins on choline transport is the very poor correlation between phospholipase activity and inhibitory potency. A more subtle mechanism of action involving factors other than or, at least, in addition to phospholipase A activity is therefore indicated.

Taipoxin is a ternary complex of three separate, but homologous peptide chains⁷ which differ strikingly in their charge properties. The α component is very basic, the β component is neutral, and the γ component is very acidic⁷. Previous studies at the neuromuscular junction have shown that the α component is the only one of the three which has appreciable blocking action by itself^{6,7}. The same applies for the effect of the individual chains on choline transport (Table 2). In fact, all of the presynaptic snake venom neurotoxins for which data are available are either very basic polypeptide chains or contain such a chain as an essential subunit. These observations indicate that a positive charge might be important for toxicity and that ionic binding to the external membrane, which presumably has a negative charge, might thus be a prerequisite for the action of these toxins. That a highly charged molecule like protamine can also block choline uptake (Table 2) supports this view, but whereas the inhibition by protamine is reversible the toxin-induced block is not (M.J.D. and J.P.F., in preparation).

We do not yet know how specific the action of these presynaptic toxins is. Recent observations on the inhibition of high-affinity choline uptake in rat brain synaptosomes by β -bungarotoxin¹⁵ agree well with our results and suggest that some part of the high-affinity uptake mechanism might constitute the 'target' for these toxins. Alternatively, the toxins might interact with sites elsewhere on the presynaptic membrane, but thereby cause some general perturbation which

Fig. 2 Effect of toxin addition on ^3H -choline accumulated by T sacs. Fraction P_2 (about 2 mg protein in each case) from *Torpedo* electric organ was incubated in 32 ml of *Torpedo* Ringer containing ^3H -choline 1 $\mu\text{Ci ml}^{-1}$ (specific activity 1 Ci mmol⁻¹) at room temperature. Samples of 1 ml were filtered at the times indicated and the accumulated ^3H determined. After incubation for 10 min the remaining T-sac suspension (22 ml) was transferred (two equal portions) to separate vessels containing either a small vol of Ringer (control) or the same vol of Ringer containing toxin. Samples (1 ml) were filtered alternately from each of these suspensions at 1-min intervals over the next 20 min; \circ , controls; \bullet , toxin treated. *a*, Taipoxin, 0.1 $\mu\text{g ml}^{-1}$ final concentration. *b*, β -bungarotoxin, 1 $\mu\text{g ml}^{-1}$. *c*, To demonstrate that gross lysis of T sacs does lead to loss of accumulated ^3H -choline, bee venom phospholipase A (Sigma) was added at a total concentration of 3 $\mu\text{g ml}^{-1}$. Each plot represents the result with different T-sac preparations. Arrows represent times of toxin addition.

Table 2 Importance of positive charge for inhibition of choline uptake

Agent tested	Concentration range studied ($\mu\text{g ml}^{-1}$)	Concentration ($\mu\text{g ml}^{-1}$) causing 50% inhibition of choline uptake
α -chain Taipoxin (basic)	0.01–10	0.3
β -chain Taipoxin (neutral)	0.01–10	> 10 (90% of control at $10 \mu\text{g ml}^{-1}$)
γ -chain Taipoxin (acidic)	0.01–10	> 10 (120% of control at $10 \mu\text{g ml}^{-1}$)
Protamine (very basic)	0.1–100	0.4

Concentration-dependent inhibition of choline uptake into T sacs was measured as described in the legend to Fig. 1 using simultaneous exposure of T sacs to ^3H -choline and toxins (or protamine) for 10 min at room temperature. Protamine was used to test whether or not the binding of a positively charged macromolecule to the T-sac external membrane alone could cause inhibition of choline transport, which it does. Other experiments have shown that, unlike the toxins, the inhibitory influence of protamine is fully reversible. The molecular weights of the agents are as follows: α subunit, 13,800; β subunit, 13,500, γ subunit, 18,400 and protamine, $\approx 8,000$.

upsets membrane-associated processes including choline transport. That taipoxin and notexin can also interfere with vesicle recycling at the neuromuscular junction⁶ supports the idea of a generic attack on presynaptic membrane-dependent processes. It seems unlikely that blockade of choline uptake is a secondary effect of inhibition of vesicle recycling since for taipoxin the blockade is instantaneous (Fig. 2). A strong case for general membrane perturbation has been presented recently for β -bungarotoxin¹⁶. We are currently attempting to localise and identify the 'target' site by using radiolabelled toxins.

This work was supported in part by an EMBO Fellowship to J.P.F. We thank Dr E. Karlsson for *siamensis* 3 neurotoxin.

vitro is related to a physiologically relevant receptor for benzodiazepines *in vivo*. We report here that benzodiazepine receptors are also present in the human brain, that the cerebral and cerebellar cortical regions contain the highest densities of binding sites and that the receptors in human brain are very similar to those in rat brain.

The brains of four humans, two males and two females, aged 18, 32, 54, and 72 yr and dying from malformatio congenita cordis, ulcus duodeni, stenosis valvulae mitralis and arterio sclerosis were investigated. No patients had a recorded history of benzodiazepine treatment within 14 d of death. Autopsies were carried out 17–72 h after death and 0.4–1.8 g of brain tissue was excised and frozen at -70°C until analysis within 14 d (experiments with rats showed that the affinity constants and density of binding sites can be safely determined 1–3 d after cessation of lorazepam or diazepam treatment, and that brains, left for 6 h at room temperature and then for 3 d at 4°C , have normal receptors). White matter contamination of grey matter was kept to a minimum, and grey matter contamination of white was avoided. The regional distribution of specific ^3H -diazepam binding sites was similar in all the brains. Table 1 therefore presents the average values from two to four brains. The receptor binding assay² consisted of an osmotically shocked crude synaptosomal preparation which was incubated for 40 min at 0°C with 0.57 – $11.3 \text{ nM } ^3\text{H}$ -diazepam (*N*-methyl- ^3H), $14.4 \text{ Ci mmol}^{-1}$ (kindly donated by Willy Haefely of F. Hoffman-La Roche). After incubation, the receptor–ligand complex was separated by filtration through glass fibre filters and measured by scintillation counting. All binding

Fig. 1 Correlation between K_i values for ^3H -diazepam displacement of 13 clinically active benzodiazepines (the average for frontal and cerebellar cortex, from Table 2) and clinically recommended dosages (Danish Physicians desk reference to pharmaceutical specialities¹⁰). The K_i -values for rat brain benzodiazepine receptors¹⁸ are also shown. The best curve fit was calculated by linear regression analysis. Numbers on graph indicate drug number in Table 2. *a*, $r=0.974$; $P<0.001$. *b*, $r=0.631$; $P<0.05$.

High densities of benzodiazepine receptors in human cortical areas

THE presence of brain-specific benzodiazepine receptors in membranes from rat brain is now established^{1–4}. Highly significant correlations between the affinities of various benzodiazepines for the benzodiazepine receptor site in rat brain on the one hand and clinically predictive pharmacological activities in several species on the other, strongly suggest that the benzodiazepine receptor *in*

Table 1 Benzodiazepine receptors in various regions of the human brain

Brain region ²⁰	Specific ³ H-diazepam binding (c.p.m. per assay)	Density of ³ H-diazepam receptors (pmol per g protein)	K_D (nM)	IC ₅₀ (nM)	
				Diazepam	Clonazepam
Frontal lobe cortex (gyrus frontalis inf.)	960 ± 200 (3)	860 ± 130 (3)	3.5 ± 0.3 (3)	22 ± 8 (3)	6.6 ± 0.7 (3)

The value for 'specific binding' represents the control binding (c.p.m. per assay, corresponding to 10 mg original tissue) at 1.9 nM ³H-diazepam used for IC₅₀-value determinations (see Table 2). The receptor densities were determined by Scatchard analysis (0.57, 1.6, 4.5, 11.3 nM ³H-diazepam, each in triplicate). In all regions Ro 5-4864 (300 nM) displaced less than 50% of specific ³H-diazepam binding. Values are the mean ± s.e.m. of (*n*) different brains, each assayed once. Nonspecific binding of ³H-diazepam amounted to 9–60% (120–200 c.p.m. per 10 mg wet tissue, at 1.9 nM ³H-diazepam) of total binding, depending on the region.

values were calculated as specific binding, defined as binding displaceable by 3×10^{-6} M unlabelled diazepam.

Table 1 shows the regional distribution of specific benzodiazepine receptors in the human brain. The densities of binding sites (determined by Scatchard analysis) show marked regional variations. The frontal cortex, occipital cortex, cerebellar cortex, temporal cortex and hippocampus contained the highest densities of specific binding sites (~700–900 pmol per g protein); intermediate densities were noted in corpus striatum, globus pallidus and hypothalamus (inclusive mammillary body) while corpus callosum, nucleus dentatus and pons showed low densities. In independent assays, the amount of specific binding was determined using a fixed concentration of ³H-diazepam (1.9 nM). These values paralleled the receptor densities determined by Scatchard analysis. The high levels of specific ³H-diazepam binding in cortical areas and the low levels in pons and medulla are very similar to the distribution in the rat brain^{2,3}.

Neuropharmacological data suggest that the hippocampus is a significant site of benzodiazepine action although several other brain areas have also been implicated¹⁷. Our results suggest that in addition to hippocampus, cortical areas may be important for the action of benzodiazepines.

Table 2 Inhibition of specific ³H-diazepam binding (1.9 nM) to human brain membranes by benzodiazepines

No.	Compound	K_i (nM)	
		Frontal cortex	Cerebellar cortex

Serial dilution of benzodiazepines in duplicate were added to the high-affinity binding assays from either frontal cortex or cerebellar cortex. K_i values were calculated using the equation: $K_i = IC_{50}/(1 + (C/K_D))$; IC_{50} is the concentration causing 50% inhibition of specific ³H-diazepam binding; C = ³H-diazepam concentration (1.9 nM) and K_D = affinity constant (3.5 and 4.2 nM, Table 1). Each value is the mean of two or three determinations with a range less than $\times 2.5$.

The apparent affinity constants (K_D) were about equal in most areas (3–7 nM) and similar to the K_D values for the rat brain receptor (2.6–3.6)^{2,4}. Only two areas, the corpus callosum and the medulla oblongata, exhibited K_D values appreciably above 7 nM indicating that the specific binding of ³H-diazepam in these areas, which also exhibited low binding, is different in nature compared with other brain areas. The Scatchard analysis of the different regions showed no tendency for binding to resolve into more than one component showing the presence of only one receptor type. A single receptor is also indicated by the similar 50% displacement values (IC₅₀) for clonazepam and diazepam in several brain regions, as well as parallel K_i values for 13 benzodiazepines in frontal cortex and cerebellar cortex (Table 2).

Brain-specific ³H-diazepam binding in the rat is characterised by high affinities for ³H-diazepam ($K_D \sim 3$ nM) and clonazepam, but low affinity for the pharmacologically inactive benzodiazepine Ro 5-4864 (ref. 2). In contrast, a specific ³H-diazepam binding site in homogenates of rat kidney and liver exhibits low affinity for ³H-diazepam ($K_D \sim 40$ nM) and clonazepam and very high affinity for Ro 5-4864 (ref. 2). The findings that clonazepam and diazepam have high, and Ro 5-4864 low affinities for the ³H-diazepam binding site in all human brain regions suggest that this site is analogous to the brain specific site in rat and different from the site in rat kidney and liver.

There were no clear correlations between the regional distribution of ³H-diazepam binding site and the regional distribution of dopamine⁵, dopamine receptors^{6,7}, noradrenaline⁵, noradrenaline receptors^{6,8}, dopamine- β -hydroxylase (in the rat)⁹, 5-hydroxytryptamine (5-HT)⁵, 5-HT receptors⁶, acetylcholine (in the cat)⁵, acetylcholine receptors⁶, choline acetylase^{5,6}, γ aminobutyric acid (GABA)^{5,6}, GABA-receptors^{6,10}, glutamic acid decarboxylase^{6,11}, endorphins (unspecified¹² or rat¹³), opiate receptors^{6,14} and substance P (refs 15, 19). Only GABA, bicuculline binding sites (in the rat¹⁰), etorphine binding sites¹⁴ and the benzodiazepine receptors exhibit the rather unusual pattern of high levels in cerebral cortex and appreciable amounts in the cerebellar cortex.

The ability of several clinically active benzodiazepines to displace ³H-diazepam from the receptors (K_i values) from both frontal cortex and cerebellar cortex correlate with the recommended daily clinical doses (Fig. 1), with an *in vivo* test for human anti-anxiety¹⁷ ($r = 0.736$; $P < 0.025$) and with the K_i values for the rat brain receptor (Fig. 1). These results further demonstrate the similarity between the benzodiazepine receptors in human brain and those in the rat brain, and suggest that they are involved in the clinical effects of benzodiazepines.

Altered exploratory behaviour after 6-OHDA lesion to the dorsal noradrenergic bundle

IN spite of the considerable evidence about the behavioural functions of brain dopamine (DA), and especially the nigrostriatal tract¹⁻⁹, relatively little is known about the functions of noradrenergic (NA) systems. Although they were initially suggested to be involved in learning^{10,11} and the coding of reinforcement¹², this is now clearly no longer tenable¹³⁻¹⁷. Perhaps the best documented function of the dorsal noradrenergic bundle^{18,19} is in extinction situations¹³. The actual behavioural mechanism involved in these situations, and how it is altered by the lesion, remains complex although some progress has been made in its elucidation²⁰⁻²². We report here what may prove to be a new class of behavioural deficit produced by selective destruction of NA systems. It was found that the response to novelty was altered in two different test situations after the lesion.

Ten male albino Woodlyn rats weighing about 300 g, received 4 µg of 6-hydroxydopamine (6-OHDA) injected stereotactically into the fibres of the dorsal bundle. Ten control animals received sham operations. The animals were allowed to recover for two weeks before behavioural testing started. After testing the ten treated and four of the control animals were killed and their brains assayed for NA²³. This confirmed that the injection of 6-OHDA had produced severe depletion of forebrain NA (cortex-hippocampus to 3.9% of control values and hypothalamus to 25.5% of control). It is known from previous work using this same technique that no alteration occurs in the concentration of brain DA¹⁵. Behavioural testing consisted first of an examination of the exploratory behaviour in a complex, structured situation comprising a series of parallel runways²⁴, and second of the investigatory response of the animal to the introduction of a novel object into a familiar cage. Nine treated and nine control animals were deprived of food for 24 h, placed in the start box of the maze apparatus and a few seconds later the door leading to the alleyways was raised. Measures taken included the time to emerge from the start box into the alleyways, the number

of alleyways entered in successive 3-min periods for a total of 21 min and the total time spent in the goal box before consumption of the first of four food pellets present there in a small elevated food cup. The 21 min of alleyway exploration started as each animal emerged from the start box and so was not contaminated by any possible difference in the emergence time between the two groups.

The number of alleyways entered per 3-min period is shown in Fig. 1; treated animals showed considerably more exploration than controls. (Alleys entered in the total 21-min period; treated mean = 96.3, control mean = 65.6, Mann-Whitney²⁵ $U = 9$, $P < 0.01$.) The time course (Fig. 1) revealed that the difference lay not in the initial rate of exploration in the first 3 min in the apparatus, but in the habituation to the novel situation with continued exposure. The treated rats also took longer to emerge from the start box (treated mean = 104 s, control mean = 46 s, Mann-Whitney $U = 22$, $P < 0.05$) and took longer to consume the first food pellet following entry to the goal box (treated mean = 91.5 s, control mean = 20.6 s, Mann-Whitney $U = 15$, $P < 0.05$). Thus, it seems from this experiment that exploration may be increased by the 6-OHDA lesion, possibly by a failure to habituate to the novel environment; to test this further, a second experiment was carried out.

The same animals (ten treated and ten controls) that had been used previously were placed on an *ad libitum* diet for 2 d and then habituated to a wooden cage for 15 min. During this period the number of times the animals crossed the line dividing the cage in two along the long axis was recorded as an index of spontaneous locomotor activity. At the end of a 15-min period the animal was removed

Fig. 1 The mean number of alleyways entered in a 3-min period plotted against successive periods for a total of 21 min in the 'parallel runway' apparatus for control and 6-OHDA-treated animals. Treated rats received stereotaxic injections of 4 µg of 6-OHDA base (obtained as 6-OHDA HBr.) dissolved in 2 µl of 0.9% saline with 0.3 mg ml⁻¹ ascorbic acid antioxidant infused at the rate of 0.2 µl min⁻¹ over 10 min at the coordinates AP2.6, ML1.1 and DV3.7 according to König and Klippel. Controls were anaesthetised, positioned in the stereotaxic and burr holes drilled at these coordinates. The stars indicate that the two groups differed significantly at that time point. One star at the 5% level, and two stars at the 1% level. NS, No significant difference between the groups. ○, Control animals ($n = 9$); ●, treated animals ($n = 9$).

briefly and a novel object (cylinder 4.5 inch by 2.5 inch in diameter) was placed in one side of the apparatus and the rat replaced in the opposite side. The latency of the first approach to the novel object was noted, as was the total time spent in contact with the object over the next 15 min. Although no alteration in the latency to approach the novel object was found (treated mean = 7.4 s, control mean = 7.9 s), the time in contact was significantly higher for the treated animals (treated mean = 79.8 s, control mean = 40.0 s, Mann-Whitney $U = 20$, $P < 0.05$). This suggests that, in this simple situation as well, the lesion increased the amount of exploratory behaviour shown towards a novel object. The number of times that the rat initiated a bout of exploration aimed at the novel object was also recorded and this did not differ from controls (treated mean = 30.3, control mean = 22.2, $U = 39$, not significant) suggesting that the lesion had not altered the frequency of initiation of an exploratory bout, but since the total time in contact with the object was increased in the treated rats, had rather interfered with the ability to habituate to that object and stop exploration. The locomotor activity counts during the habituation phase before introduction of the novel object rule out either hyper- or hypoactivity as the cause of the increased exploration, since no difference was found between treated and control animals (treated mean = 29.7, control mean = 23.7, $U = 43$, not significant), and this has also been shown several times in other situations³⁰. A second locomotor activity measure taken on these same rats in photocell cages confirmed this (treated mean = 790 beam interruptions in 21 min, control = 976, t statistic = 1.61, not significant). We have since replicated these two exploration experiments with identical results in another group of animals depleted of brain NA.

The results reported here add to the few functions already demonstrated^{13,14,17} for NA systems. Since our lesions resulted in severe depletion of hypothalamic NA as well as cortical-hippocampal NA we cannot as yet say whether this effect is due to the dorsal NA projection from the locus coeruleus or the so-called ventral bundle arising in more posterior cell groups and innervating the hypothalamus^{18,19}. The behavioural mechanism involved must also remain indeterminate at this time. It is of interest, however, that animals with similar lesions have been shown to be resistant to extinction in a number of situations^{13,14,17}. Whether the elevated exploratory behaviour observed in the dorsal bundle lesioned animals similarly reflects impaired extinction of the exploratory response is not known. It is possible that the present observations may be yet another measure of the deficit which has been observed in other situations^{13,14,17}, or they may be due to damage to independent mechanisms possibly reflecting noradrenergic deafferentation in different terminal regions of the brain. Another possibility is that, as has been reported after locus coeruleus lesions^{26,27}, these animals may be less fearful and so tend to 'freeze' less and thus explore more. This seems less likely since the initial rate of exploration in the first 3 min in the maze apparatus did not differ from controls, suggesting that the immediate fear reaction was not altered. The subsequent habituation was retarded, however, suggesting perhaps that the treated animals might be unable to learn to overcome their fear. It has been suggested^{28,29} that the central emotional state produced by fear has similarities to that produced by frustration (caused by omission of an expected reward) and that the dorsal bundle lesioned rat may be impaired in learning about or remembering frustration (S. T. M. and S. D. Iversen, unpublished), although its general learning capacity in situations not involving frustration or similar states is unaltered¹³⁻¹⁷. An increase in the immediate baseline fear reaction is also counter-indicated inasmuch as no increase in the latency to approach the novel object immediately after its introduction was observed. Certain additional mechanisms may be tentatively

excluded since it has been shown that no deficit in internal inhibition (ref. 30 and S. T. M. and S. D. Iversen, unpublished), some forms of attention (S. T. M. and T. W. Robbins, unpublished), perseverance^{13,17,30} or general learning ability¹³⁻¹⁷ is present in these animals. The data reported here also rule out simple locomotor activity mechanisms. Further research will be required, however, to elucidate the basis of this alteration in exploratory behaviour found after depletion of forebrain NA.

S. T. M. is an MRC Fellow and the work was supported by the Medical Research Council. The technical assistance of Betty Richter is acknowledged. D. C. S. Roberts performed the 6-OHDA lesions.

Cerebral lateralisation effects in visual half-field experiments

THE systematic study of behavioural differences related to differential functioning of the cerebral hemispheres has increased markedly in recent years. The studies of Sperry and his collaborators¹ on cerebral commissurotomy patients have stimulated many investigations into the hemisphere specialisations of normally functioning subjects. There are now many reports^{2,3} of statistically significant differences in hemisphere performance. Although hemisphere differences are consistent across independent experiments, they are small, occasionally inconsistent, and found within a limited experimental context, and so the generality of hemisphere differences remains to be established. We present here brief accounts of six experiments on cerebral lateralisation, four of which failed to find any differences and two which produced highly significant hemisphere differences. On the basis of this and published work, we believe that we can offer both a possible explanation for both the presence and absence of cerebral lateralisation effects in visual half-field experiments and also procedural guidelines that will produce cerebral lateralisation effects.

Much of the method for our six experiments is identical. Adult right-handed subjects fixated on a reference point in a three-field tachistoscope and indicated readiness to the experimenter. Stimuli were then shown for a period not exceeding 150 ms to the light visual field projecting to the left hemisphere (RVF-LH), or the left visual field projecting to the right hemisphere (LVF-RH), or with one member of a stimulus pair projected to each visual field (EVF). In all experiments, stimuli were located 2.5° of visual angle from the fixation point. Illumination level was 15 ft L.

Experiment 1: Stimulus materials were 96 words selected from a list of common Chinese terms using the norms developed by Liu and Chuang⁴ and their English equivalents (most English words used have A or AA Thorndike-Lodge ratings). The Chinese stimuli were all single characters which were drawn with a felt-tip pen and spanned 0.84° of visual angle. The English words (ranged from three to six letters) were done with Letraset 20 point Helvetica and spanned horizontally 0.84°–1.30° of visual angle at maximum. Forty-eight of the pairs were direct unambiguous translations and 48 were dissimilar terms. Presentation to RVF-LH, LVF-RH, and EVF were equal and randomised. Eight subjects fluent in reading Chinese and English responded by saying 'yes' if a stimulus pair had the same meaning and 'no' if they did not. Each of the 96 stimulus pairs was shown once. No term occurred more than once.

An analysis of variance of reaction times for making correct decisions revealed a statistically significant effect ($F(1, 7) = 19.90, P < 0.01$) for same-different judgments, indicating that decisions that two terms did not have the same meaning required more time than judgments of identity. Differences between visual fields and interactions did not differ appreciably from chance levels. Mean reaction times for experiments 1–4 are given in Table 1.

Experiment 2: At random, six of the stimulus pairs used in experiment 1 were discarded. The remaining 90 were then arranged as 30 English-English pairs, 30 Chinese-Chinese pairs, and 30 Chinese-English pairs (selected from the word pairs of experiment 1). Within each 30-pair set,

15 terms were identical and 15 different. Presentation to visual fields was as in experiment 1. Each stimulus pair was shown once and no terms were repeated. Subjects were 20 Chinese-English bilinguals, fluent at reading Chinese and English, and this time a manual (instead of oral) response was used.

Data analysis was identical to that in experiment 1. Only one comparison—that for judgments of same-different—reached an acceptable level of statistical significance ($F(1, 18) = 19.60, P < 0.001$). As was found in experiment 1, judgments of sameness take less time than judgments of difference. No visual field-hemisphere differences were present. The Chinese-English EVF data from experiments 1 and 2 were further partitioned into trials in which the Chinese was on the left and the English was on the right and vice versa. No reliable effect was obtained from this contrast either.

Experiment 3: Eight monolingual English subjects made judgments of same-different to the 30 English-English pairs and 30 Chinese-Chinese pairs used in experiment 2. Stimuli were shown once, with no repetition. Manual response reaction time was taken as dependent measure. Analysis revealed no statistically significant effects for any condition. No visual field-hemisphere differences were present and differences in response time to language (Chinese against English) and type of judgments (same against different) were not significant.

Experiment 4: Eight monolingual English subjects made judgments of same-different on stimulus pairs made up of only four Chinese characters and four English words. Within each language, every word was paired with every other word for 'different' stimulus pairs and with itself for 'same'. Presentation of either the Chinese-Chinese or English-English pairs was made only to RVF-LH and LVF-RH fields for 200 trials, which were distributed over five blocks with 40 trials per block. An analysis of variance of reaction times revealed a significant interaction effect of language by visual field by trial ($F(4, 28) = 4.00, P < 0.01$). Inspection of mean values indicated that reaction time by hemisphere effects increases systematically over trials and the data in the last block show a faster reaction time to English-English stimuli in the RVF-LH and a similar, though smaller, effect for Chinese-Chinese stimuli in the LVF-RH.

Experiment 5: Seventy-five subjects made judgments of same-different on pairs of figures selected from the spatial ability subtest of the Thurstone primary mental abilities test⁵. Stimulus pairs occupied about 2.5° of visual angle, were immediately adjacent, and at either 45° or 180° of rotational difference from each other. Stimuli were defined as 'same' when rotation in a clockwise or counter-clockwise direction allowed one stimulus to completely cover the other. When stimuli were mirror images, they were defined as 'different'. Seventy-two stimulus pairs were used, each pair shown once. The types of figures used each appeared twice, although no combination was ever repeated exactly. Reaction time was not measured in this experiment, the accuracy of response being the only parameter. Analysis of variance indicated no significant effects for visual field-hemisphere, type of judgment, or degree of rotation.

Experiment 6: Six pairs of stimuli were selected at random from the stimuli used in experiment 5. Three stimuli were 'same' and three were 'different', as defined in experiment 5. Eight subjects were shown the stimulus pairs, randomly presented to RVF-LH or LVF-RH only for 200 trials. An analysis of response accuracy showed that stimuli shown in the LVF-RH are judged more accurately than the same stimuli shown in the RVF-LH and that more errors were made in the 'same' pairs than in the 'different' pairs. Mean accuracy judgments for experiments 5 and 6 are given in Table 2.

Table 1 Mean reaction times for experiments 1–4

Condition			Experiments			
			1	2	3	4
			X	X	X	X
English-English	LVF-RH	Same		1,185	1,220	767
		Different		1,310	1,017	806
	RVF-LH	Same		1,176	1,264	715
		Different		1,320	1,035	740
	EVF	Same		1,084	1,048	
		Different		1,367	1,066	
Chinese-Chinese		Same		1,093	1,087	854
		Different		1,141	1,084	796
		Same		1,188	1,085	834
		Different		1,098	1,127	794
		Same		1,057	1,202	
		Different		1,132	1,107	
Chinese-English	LVF-RH	Same	1,341	1,175		
		Different	1,976	1,722		
	RVF-LH	Same	1,413	1,355		
		Different	1,955	1,606		
	EVF	Same	1,240	1,229		
		Different	2,099	1,584		

In experiment 1, response time was taken with an electronic voice key stopping an ms-timer activated when the stimulus was shown. In experiments 2–4, it was measured by pressing one of two buttons on a horizontal panel in front of the subject, so arranged as to allow comfortable arm placement. Subjects were instructed to press one button if the members of the pair shown were the same and the other button if they were different. The index finger of each hand was used to respond, with hand used for 'same' or 'different' responses counterbalanced across subjects. The timing mechanism was that used in experiment 1.

Table 2 Mean accuracy scores for experiments 5-6

LVF-RH	Same	6.43	29.23
	Different	7.24	36.49
RVF-LH	Same	6.06	18.12
	Different	7.73	33.12
EVF	Same	7.28	
	Different	9.15	

The accuracy scores were obtained by counting the number of correct responses made by subjects across all experimental trials. The highest score possible in experiment 5 is 12 and in experiment 6 is 50.

In summary, experiments 1, 2, 3 and 5 failed to detect any sign of hemisphere differences in judgment processes. These null effects should not be attributed to the insensitivity of the experimental design, since by merely changing the ratio of trials to experimental stimuli experiments 4 and 6 both found significant hemisphere function differences, similar to those reported by other investigators⁸.

In most interpretive models of cortical processing, an individual listening to the spoken word or engaged in reading, is hypothesised as having language information sent to the left hemisphere for processing, semantic analysis and understanding. An appropriate language response is hypothetically generated within the left hemisphere. Similar formulations are proposed for visuospatial processes within the right hemisphere. Our results cannot be explained within such interpretative models.

An activation model, such as that proposed by Kinsbourne⁷, also seems unable to account for our results. Given that all judgments will be semantic comparisons or pattern matches, the expectation from an activation model is that the hemisphere specialised for such processing will be activated and will show superior performance. No such process is evident in our experiments.

An alternative explanation is that lateralisation effects often reported in visual half-field experiments are not a function of immediate cognitive processing in specialised cortical areas, but do reflect hemisphere difference in memory storage location. The experiments reported here are consistent with such a formulation. If a subject has to evaluate new information on each trial, his reaction times or his response accuracy do not differ systematically with visual field presentation. Given such a reinterpretation of lateralisation phenomena, it is important to know if others have obtained similar results using the conditions described. A review of experiments reporting significant hemisphere specialisation effects indicates the number of stimuli used to range from 4 to 64, with the number of trials from 40 to 1,072. By contrast, published accounts which report no hemisphere specialisation differences⁸⁻¹⁰ have, in general, equal numbers of stimuli and trials. It would be of interest to reanalyse data from studies reporting lateralisation effects to see if the trends found in our experiments 4 and 6 are present there. Bryden¹¹ has reported such trends but to our knowledge they have not otherwise been investigated systematically.

The interpretation of these results seems straightforward: to obtain cerebral lateralisation effects, produce a condition that allows judgments to be made from memory. Experimentally, where a new evaluation and decision must be made on every trial, there is little evidence for any lateralisation of function. When the number of stimuli to be judged are so few that the subject may adopt a new strategy and carry out simple matching from a memory set of known size, then cerebral lateralisation effects are found.

These results suggest a number of interesting possibilities for the study of specific kinds of memory storage. Decreases in response time in relation to visual field presentations also suggest an interesting way of assessing when an item is firmly committed to memory. The most important

aspect of these findings, however, is the strong implication that (1) active cognitive processes are not lateralised, and (2) interpretative models which view active cognitive processing as being lateralised are not correct. The present work gives no support to the theory that, dealing with events which require active, immediate, continuous processing of a constantly changing flow of information is limited to one hemisphere at a time.

Calcium-dependent regenerative responses in rods

NEURONES are thought to contain ion-selective channels whose opening and closing are regulated by the potential difference across the plasma membrane. It is thought that the sodium, potassium, and calcium currents which generate action potentials and modulate synaptic transmitter release pass through these channels. Investigations of voltage-dependent currents in various species have revealed remarkable uniformities in the ion selectivity and pharmacology of presumed membrane channels¹⁻³. The use of agents which block specific currents has provided a tool for the identification of voltage-dependent conductances in nerve membrane, which we have used to investigate vertebrate photoreceptors. We show here that when the retina of the toad *Bufo marinus* is superfused with Ringer containing 6-12 mM tetraethyl ammonium (TEA), rods generate oscillations and action potentials resembling the calcium spikes which have been described in various vertebrate and invertebrate preparations³. These experiments demonstrate that the rod membrane is not passive, as is often assumed, but contains at least one and probably two voltage-dependent conductances.

Retinas were removed from the eyes of dark-adapted toads under dim red illumination and were secured with receptors upwards in a perfusion chamber. Oxygenated Ringer flowed from a gravity-controlled perfusion system into a 0.03-ml pool above the retina at a rate of 0.5-1.0 ml min⁻¹. Silver-silver chloride electrodes were fixed in the chamber below the retina and above it in the perfusion pool to record the electroretinogram (ERG), and simultaneous recordings were made of intracellular responses with fine micropipettes with resistances of 200-400 M Ω . When the b-wave of the ERG reached a stable, dark-adapted threshold, a micropipette was lowered through the perfusion pool with an hydraulic microdrive. Just after reaching the retina, the pipette penetrated cells with response waveform, absolute

sensitivity, spectral sensitivity, and light adaptation characteristic of 'red' rods recorded in previous studies on toad eyecup¹. Rods were stimulated with large-field, 516 nm light from a conventional, dual-beam photostimulator. Normal Ringer had the following composition: 96 or 106 mM NaCl, 1.8 mM Na₂SO₄, 0.13 mM NaHCO₃, 2.5 mM KCl, 1.2 mM MgCl₂, 1.8 mM CaCl₂, 5.6 mM glucose, and 3.0 mM HEPES, adjusted to pH 7.8 with approximately 2 mM NaOH (Ringer modified from ref. 5). All experiments were performed at approximately 22 °C.

Since TEA has been shown to block potassium currents in nerve membrane¹, we examined its effect on the rod photoresponse. We found that 6–12 mM TEA, either added to normal Ringer or substituted for NaCl, depolarises the rod membrane by 3–5 mV. In addition, the receptor potential returns more quickly to the baseline and is followed by 3–4 Hz, regenerative oscillations (Fig. 1a). The peak-to-peak amplitude of the oscillations is initially as large as 35 mV but decays to zero within 4–5 s. After extended perfusion in TEA-Ringer, the amplitudes of the oscillations decay to zero following the light flash more

slowly than shown in Fig. 1, and eventually the oscillations become spontaneous in the dark. Similar oscillations are produced when the retina is superfused with Ringer containing 3 mM of the potassium channel blocking agent 4-aminopyridine⁶, or when the Ca²⁺ in the Ringer is replaced by Sr²⁺ or Ba²⁺. The oscillations can be recorded in the b-wave of the ERG, suggesting that the rods and second-order cells are all oscillating in phase. This is not unexpected as we stimulate the retina with a large, uniform field, and as the responses of the rods are tightly coupled by an extensive network of gap junctions⁷.

The effect of TEA on toad rods resembles that described for crustacean muscle fibres^{3,8,9} and for the presynaptic terminal of the squid giant synapse¹⁰. In these cells the membrane contains a voltage-dependent calcium conductance which, in the absence of TEA, is thought to be shunted by the development of a much larger, voltage-dependent potassium conductance. TEA seems to block a part of the potassium conductance, permitting the calcium current to become regenerative. Although we have no direct evidence that TEA is blocking a potassium conductance in rods, we have tested to see if a calcium current contributes to the oscillations in TEA Ringer by examining the effect of changes of external calcium concentration on the amplitude and duration of the oscillations. We found that as the calcium concentration is reduced, either by substituting Mg²⁺ for Ca²⁺ or by removing Ca²⁺ from the Ringer, the membrane potential depolarises, probably as the result of an increase in sodium conductance^{11,12}, and the oscillations become smaller and decay more quickly. This is shown in Fig. 1b. In 0.5 mM Ca²⁺ (right trace) the oscillations become quite small and, with prolonged perfusion, may vanish altogether. When all of the calcium is removed from the Ringer, the oscillations rapidly disappear. These effects are completely reversible if exposure to low calcium Ringer is not prolonged. In contrast, the oscillations are unaffected by the removal of Mg²⁺ from the 12 mM TEA Ringer.

Increases in [Ca²⁺] produce somewhat more complicated effects. We found that small increases in extracellular calcium cause small membrane hyperpolarisations, probably by decreasing the sodium conductance^{11,12}. Concomitant with this change in potential, there is a dramatic increase in the oscillation amplitude. In Ringer containing TEA and 2.7 mM (1.5 times normal) or 3.6 mM (twice normal) Ca²⁺, the oscillations of most cells become action potentials, up to 45 mV in amplitude and 60–100 ms in duration (Fig. 2). The action potentials are spontaneous in the dark but are interrupted by stimulation with light. The depolarising components of the action potentials are followed by 5 mV hyperpolarising undershoots, which decay to the baseline in 0.5–1 s. If the concentration of Ca²⁺ is increased to 5–16 mM, the rod is further hyperpolarised, and both the action potentials and oscillations are suppressed. We believe that the suppression of the spikes in high Ca²⁺ concentration may simply be the result of the hyperpolarisation of the membrane potential below the spike threshold. Our reason for thinking this is that large spontaneous action potentials can be recorded when high concentrations of Sr²⁺ are added to TEA Ringer containing normal Ca²⁺ (1.8 mM). For the rods, as for many other nerve and muscle cells³, Sr²⁺ seems to be able to substitute for Ca²⁺ as a current carrier in calcium action potentials. Unlike Ca²⁺, however, Sr²⁺ has little effect on the rod membrane potential. As the Sr²⁺ concentration is increased, the amplitude of the action potential increases continuously, and in 28 mM Sr²⁺ the spikes are nearly 60 mV.

To provide further evidence for the identification of the mechanism producing the oscillations, we studied the effects on the TEA-induced responses of agents known to block calcium channels^{2,3}. We found that the oscillations were reversibly blocked by the addition of low concentra-

Fig. 1 TEA-induced oscillations in toad rods. *a*, *b*, and *c*, from different retinas. Each shows representative records taken from one continuous recording from a single rod in a dark-adapted retina. All responses are to 109-ms flashes of 516 nm, full-field illumination. *a*, Effect of TEA on rod responses. Left trace, response in normal Ringer (see text). Middle trace, after changing to Ringer containing 12 mM TEA chloride substituted for NaCl. Note 3.5 mV depolarisation of the dark membrane potential, faster decay of receptor potential toward baseline, and oscillations. Right trace, after return to normal Ringer. Membrane potential has repolarised, and the receptor potential waveform has returned to that observed initially. Stimulus intensity for each response was 9.3 log quanta per cm² per flash. *b*, Ca²⁺ dependence of rod oscillations. Left, response in Ringer containing 12 mM TEA and normal Ca²⁺ concentration (1.8 mM). Middle, in 12 mM TEA Ringer containing 1.0 mM Ca²⁺. Note 5 mV depolarisation of membrane potential and decreased amplitude and duration of oscillations. Right, in 12 mM TEA and 0.5 mM Ca²⁺. Membrane potential has depolarised 11 mV from that observed in TEA and normal Ca²⁺. Oscillations have nearly disappeared. Stimulus intensity: 9.8 log quanta per cm² per flash. *c*, Oscillations blocked by Co²⁺. Left, response in Ringer containing 12 mM TEA. Middle, in Ringer containing 12 mM TEA and 50 μM Co²⁺. Note slower decay of response to baseline and decreased amplitude of oscillations. Right, in Ringer containing 12 mM TEA and 100 μM Co²⁺. Oscillations have disappeared. Stimulus intensity: 9.8 log quanta per cm² per flash.

tions of cobalt chloride (Fig. 1c). In $50 \mu\text{M}$ Co^{2+} (Fig. 1c, middle trace), the effect of TEA on the decay of the response is partially reversed (that is, the decay to the base line becomes much slower than in normal TEA Ringer), and the oscillations are smaller and begin several seconds after the decay of the photoresponse. In $100 \mu\text{M}$ Co^{2+} (Fig. 1c, right trace), the oscillations disappear. The oscillations are also reversibly blocked by Mg^{2+} , but the required concentration is much higher (2.5–5 mM). A greater sensitivity to Co^{2+} than to Mg^{2+} has been previously observed for calcium currents in crustacean muscle and for transmitter release^{3,13}. The drug D-600, which has been shown to block the late phase of calcium entry in squid axon¹⁴, also produces a reversible block of rod oscillations at a concentration of 10^{-4} M.

In contrast to Co^{2+} , Mg^{2+} and D-600, tetrodotoxin at $2 \mu\text{M}$, a concentration more than sufficient to block sodium currents in axons¹, has no effect on the rod oscillations. The substitution of choline chloride for NaCl in the Ringer eliminates the oscillations, but this procedure also produces a large hyperpolarisation of the rod membrane potential⁵. In choline chloride Ringer containing 28 mM SrCl_2 , rods generate 35–40 mV, spontaneous action potentials. This experiment shows that sodium is not necessary for the generation of regenerative responses in rods but does not exclude the possibility that sodium currents contribute to the oscillations in normal Ringer.

The results described above are not incompatible with the possibility that the oscillations are caused by an interaction between receptors and second-order cells, since changes in Ca^{2+} concentration or the addition of Co^{2+} or Mg^{2+} to the Ringer could also affect synaptic transmission. In fact, Normann and Pochobradsky¹⁵ have reported spontaneous oscillations in the membrane potential of toad rods which they believe to be caused by such interactions. We have not been able to examine the possible relation between the spontaneous oscillations of Normann and

Pochobradsky and the TEA-induced regenerative responses we report, as we have never observed spontaneous oscillations in rods superfused with normal Ringer. It is unlikely, however, that the regenerative responses we have described are caused by synaptic interactions. The addition to the Ringer of 2 mM sodium aspartate, which has been shown to block the responses of second-order horizontal and bipolar cells in the retina^{5,15–17}, has no effect on the amplitude or frequency of TEA-induced oscillations, even though in our experiments sodium aspartate blocks the simultaneously recorded b-wave of the ERG.

Our results suggest that the oscillations and action potentials produced by the rods in the presence of extracellular TEA are caused by regenerative calcium currents. We cannot as yet exclude a contribution to the oscillations from an inward-going sodium current; however, the dependence of oscillation amplitude on external calcium concentration, the extreme sensitivity of the oscillations to external Co^{2+} and D-600, and their insensitivity to tetrodotoxin all argue against a major role for sodium. Furthermore, the spikes in high Ca^{2+} TEA Ringer have a time course resembling that of calcium spikes in other systems³, being much slower in rise time and longer in duration than that of any sodium spike so far described.

Although we believe that calcium carries the inward current which produces the rising phase of the spikes and oscillations, we are uncertain of the mechanism for their falling phase. It seems unlikely that the repolarisation is caused by inactivation of the calcium conductance, as calcium inactivation in other systems seems to be too slow^{3,18,19}. We have tested for a possible role for a chloride conductance by replacing all the NaCl in the TEA Ringer with sodium isethionate, but we found no effect on the oscillations. We suggest that, in addition to a calcium conductance, the rod membrane contains a voltage-dependent or calcium-activated potassium conductance, which is only partially blocked by external TEA.

We have no evidence as to the location of the presumed calcium channels in the rod membrane or their possible functional significance, though we suppose that at least part of the calcium conductance is involved in synaptic transmitter release. Our recordings are probably made from the outer segment of the rod^{20–22}, but it is possible that the oscillations are generated near the synaptic terminal and spread passively to the distal end of the receptor.

We thank Mr Bernard Lacaille for constructing the perfusion chamber and photostimulator and Dr S. Hagiwara for reading a draft of the manuscript. This investigation began in Paris with the assistance of an exchange fellowship to G.L.F. from Harvard University and The Institut National de la Santé et de la Recherche Médicale, France. The work was supported by grants from the DGRST (74-7-0385) and CNRS (ATP 1288) to H.M.G.; from the Norton Simon Foundation, Fight For Sight, Inc. and the NIH (EY 01844) to G.L.F.; and by a postdoctoral traineeship (EY 7026) to F.N.Q.

Note added in proof: Measurements of the current-voltage curve of rods in normal Ringer show a region of outward-going rectification positive to the dark membrane potential which is markedly reduced in 12 mM TEA. Calcium-dependent regenerative responses have also been recorded from the presynaptic terminal of barnacle photoreceptors²³.

Ionic interactions in the potassium channel of squid giant axons

ONE of the simplest questions that can be asked about how ions cross biological membranes is whether or not they do so independently of one another. That is, is the probability of movement of an ion unaffected by the presence of other ions? In particular, with independent movement, the efflux of an ion should not be a function of the external concentration of that ion. Using long-lasting depolarisations, Hodgkin and Keynes demonstrated¹ non-independent movement of K^+ ions across the membrane of *Septa* axons. Since the Na channel responsible for initiation of the action potential inactivates very rapidly on depolarisation, potassium ions were probably not moving through this pathway—even though the channel is permeable to them as well as to Na^+ ions. But since the K channels (partly responsible for termination of the action potential) also inactivate on prolonged depolarisation², the K efflux measured by Hodgkin and Keynes was presumably mainly through inactivated K channels and the so-called 'leakage pathway'. We report here on experiments that demonstrate non-independent ion movement through the activated K channel of the giant axon of *Loligo pealei*, using tetrodotoxin to block the Na channels, and short-step depolarisations to minimise K-channel inactivation.

Techniques for membrane voltage measurement and control have been described previously³. The axons were perfused internally with a solution containing 400 mM potassium labelled with ^{42}K . The artificial seawater (ASW) bathing the axons contained various K concentrations up to 75 mM. All experiments were done with a holding potential of -78 mV, and the data obtained with 20–40-mV depolarisations lasting for 20–30 ms. These pulses opened a sufficient number of K channels to produce measurable flux rates, yet were small enough to minimise K loading of the periaxonal space. Even so, some K loading into the 5 or 20 mM K-ASW solutions was detected from the reversal potential at the end of the depolarising pulse. To obtain a 'mean' value of external K during the pulse, we averaged the nominal K concentration in the ASW and the value computed from the reversal potential. Very little loading was observed for the 'high K' solutions. More refined averaging procedures would not alter the conclusions of the study.

Figure 1 shows ^{42}K efflux into ASW containing either 20 or 5 mM K. As expected, resting ^{42}K efflux from this hyperpolarised axon ($2\text{--}4\text{ pmol cm}^{-2}\text{ s}^{-1}$) was lower than that reported for axons at rest^{4,5}. For a period of 7.5 min the membrane voltage was clamped once every 300 ms to a potential of -53 mV for 30 ms. The isotope efflux quickly increased during this period to a constant value, and rapidly returned to the low values following cessation of the pulses. With the membrane potential still maintained at -78 mV, the external solution was then changed to one containing only 5 mM K. After a 7.5-min control period, the same stimulation procedure was repeated. The efflux during repetitive

Fig. 1 Potassium efflux from an axon perfused internally with a solution containing 400 mM K^+ (labelled with ^{42}K) into artificial seawater (ASW) containing 20 (a) or 5 (b) mM K^+ . The perfusion solution contained (in mM): K glutamate, 320; KF, 50; sucrose 260; K phosphate, 30; pH 7.3. Perfusion pressure was produced by a motor-driven syringe delivering about $2\text{ }\mu\text{l min}^{-1}$. ASW composition was as follows (in mM): NaCl + KCl, 430; $MgCl_2$, 25; $MgSO_4$, 25; $CaCl_2$, 10; EDTA, 0.2; Tris-HEPES (pH 7.8), 5. ASW was delivered, at 2.7 ml min^{-1} , to the centre of the experimental chamber (volume ~ 0.5 ml) by a peristaltic pump, removed by two pumps (0.9 ml min^{-1} each) through outlets located 3 mm on either side of the inlet, and collected in 1.5-min aliquots. The remainder of the flow was removed by suction through outlets located at the outermost edges of the chamber, and discarded; this was done in order to prevent collection of ^{42}K originating from imperfectly clamped regions of the axon ('end-effects'). The axon membrane voltage was held at -78 mV throughout the experiment, except during the periods indicated by the horizontal bars, when the axon was depolarised by a 25-mV, 30-ms rectangular pulse every 300 ms.

depolarisation was about twice that in the 20-mM solution; any spontaneous deterioration of the axon could only have caused an underestimation of this difference. Our voltage-clamp records showed little or no effect of external potassium on the kinetics of opening or closing of the K channels.

Figure 2 shows a similar record for another fibre, first in 50 mM K and then in 20 mM K-ASW, depolarised once every 200 ms by 40 mV for 30 ms. Since many more K channels are opened at -38 mV than at -53 mV, extra efflux here was much larger than that in the experiment of Fig. 1. Again, the efflux was greater into the solution containing the lower K concentration. After about 45 min, 2 mM 4-aminopyridine was added to the ASW. This compound is known to block the 'late' (that is, potassium) channels of giant axons^{6,7}. In the present experiment, the late outward current was reduced to less than 10% of control; extra ^{42}K efflux was also reduced to very low levels by this treatment, suggesting that a very large proportion of the measured flux in our experiments took place through K channels rather than 'leakage' pathways.

Fig. 2 Effect of external potassium ions and 4-aminopyridine on ^{42}K efflux. Experimental procedures were as in Fig. 1. Holding potential was -78 mV throughout the experiment. During the periods indicated, the axon was depolarised by a 40-mV, 30-ms rectangular pulse every 200 ms. a, 50 mM K^+ ; b, 20 mM K^+ .

The results of our experiments are summarised in Fig. 3. The ^{42}K efflux (normalised to the value for 20 mM K-ASW) is plotted against external K concentration for two values of the depolarising pulse (30 and 40 mV). In both cases ^{42}K efflux decreases with increasing external [K], in violation of the independence principle. The relative inhibitory effect of external K on ^{42}K efflux, however, seems stronger for smaller depolarising pulses. (In additional experiments with 20-mV pulses, this trend was continued.)

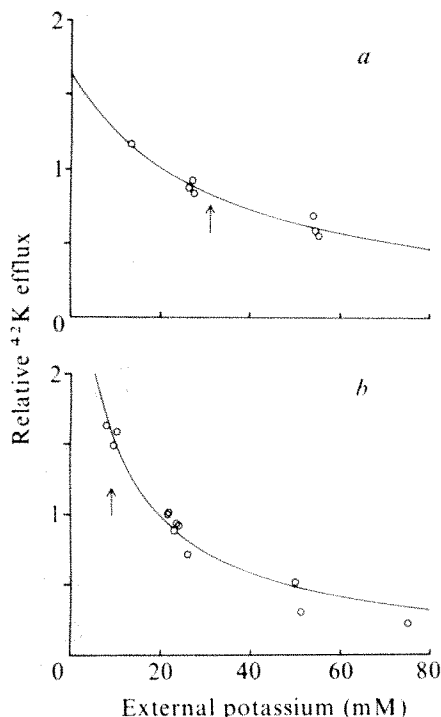

Fig. 3 Relative inhibition, by potassium in the seawater, of ^{42}K efflux through K channels of squid giant axon, for two different clamping pulse sizes. (See Fig. 1 for experimental procedures.) For each of the two pulse sizes: 40 mV (a), 30 mV (b), the fluxes were scaled to unity at 20 mM external K. Both sets of data were adequately fitted by simple adsorption isotherms of the form

$$\text{Flux} = \text{Flux}_{\text{max}} K_i / (K_i + [\text{K}]_o)$$

where K_i is the dissociation constant of a monomolecular reaction between external potassium and some site in the K channel, which results in blockage of ^{42}K efflux. The respective K_i values are indicated by arrows on the graphs. The apparent affinity of the channel site for external potassium is higher at the more negative clamping potential. This trend was continued in a few experiments (not shown) with 20-mV pulses (at -58 mV clamping potential).

The nature of the interaction of external K^+ ions with the K channel of squid axon membrane is unknown. Our data are consistent with the single-file model described by Hodgkin and Keynes for K^+ flux across steadily depolarised *Sepia* nerve membrane, but more work is needed to test detailed models. The most economical description of our data is to say that the activated K channel contains a site which, when occupied by external K, prevents efflux of internal ^{42}K . The dissociation constant of the potassium-site complex is of the order of 10^{-2} M, and decreases with increasing membrane potential.

Permeant cations alter endplate channel characteristics

At amphibian neuromuscular junctions, the binding of acetylcholine to postsynaptic receptors opens endplate channels. An endplate current (e.p.c.) is generated as sodium and potassium ions flow through these channels according to their electrochemical gradients¹. In normal conditions the e.p.c. is a net inward current of predominantly sodium ions. It has been shown that the lifetime of endplate channels is affected by temperature^{2,3} and membrane potential³, depends on the nature of the cholinergic agonist^{4,5} and can be influenced by various chemicals and drugs^{6,7}. But, it is not known what normally determines the lifetime and conductance of an open channel. We report here that the nature of the permeating cations that generate the e.p.c. affects the lifetime and conductance of endplate channels. These observations indicate that these cations influence the mechanisms that determine channel behaviour.

Endplate channel characteristics were compared for three different permeating cations—sodium, lithium and caesium. Normal extracellular solution (sodium solution) contained 115 mM NaCl, 2.5 mM KCl, 1.8 mM CaCl_2 and 3 mM phosphate buffer. Lithium and caesium solutions were made by replacement of NaCl with 115 mM LiCl or 115 mM CsCl respectively. The pH of all solutions was 7.2 and experiments were performed at 20 °C.

Spontaneous miniature end-plate currents (m.e.p.cs) and current fluctuations (noise) generated by iontophoresis of acetylcholine were recorded in voltage-clamped fibres in sartorius muscles of toads (*Bufo marinus*) using techniques described previously^{8,9}. In most cases muscles were glycerol-treated to prevent contraction when fibres were depolarised. For analysis of acetylcholine noise, 8,192 or 16,384 data points, filtered by two low-pass, cascaded Butterworth filters in series (40 dB per decade roll-off) with cut-off at 800 Hz were sampled at 2 kHz. A fast Fourier transform method was used to analyse the frequency components of the noise and determination of single channel conductance and average lifetime was based on the model and theory described by Anderson and Stevens³. Lorentzian curves were fitted to data using a least squares fitting method.

In the solution containing lithium (lithium solution), the time constant of decay m.e.p.cs was significantly greater than the normal extracellular solution. This is illustrated in Fig. 1. Averages of 20 m.e.p.cs in normal (sodium) solution and 20 m.e.p.cs in lithium solution are shown in Fig. 1a. These m.e.p.cs were recorded in a fibre voltage-clamped at a membrane potential (V_m) of -70 mV. The decay phase remained exponential in lithium solution as is clear from the semilog plots of the decay phases of the same currents shown below (Fig. 1b). In this experiment the average decay time constant (τ_d) was 2.5 ms in sodium solution and 3.3 ms in lithium solution. The lengthening of m.e.p.cs seen in lithium solution could be reversed by returning to sodium solution. In addition to the increase

Fig. 1 Miniature endplate currents recorded in a muscle fibre voltage-clamped at -70 mV in sodium (Na) and lithium (Li) solutions. *a*, Averages of 20 m.e.p.cs in the two solutions. *b*, Semilogarithmic plots of the decay of the averaged m.e.p.cs (note normalised peak amplitudes) in sodium (Δ) and lithium (\bullet) solutions. The fitted lines are regression lines (correlation coefficients 0.999 and 0.998) and gave time constants of 2.5 ms and 3.3 ms in the sodium and lithium solutions respectively. (Temperature 20°C .)

in decay time constant, there was a decrease in the average amplitude of m.e.p.cs in this experiment from 2.3 ± 0.09 nA in the sodium solution to 1.46 ± 0.06 nA in lithium solution (mean \pm s.e.m.). This depression of m.e.p.c. amplitude was also reversible. The reduction in m.e.p.c. amplitude could not be explained by changes in acetylcholine null (reversal) potential (ϵ_s). ϵ_s was directly measured in each of the solutions by determining the potential at which there was no increase in current when acetylcholine was applied iontophoretically to an endplate. In seven fibres in lithium solution, the null potential was -6.1 ± 1.1 mV and in 15 fibres in sodium solution the null potential was -2.9 ± 0.5 mV. The increase in the time constant of decay and decrease in amplitude of m.e.p.cs caused by lithium were consistent with the increased lifetime and decreased conductance of individual endplate channels as determined by analysis of acetylcholine current noise. Logarithmic plots of spectral density against frequency obtained at the same endplate are shown in Fig. 2 for sodium (Na) and after exposure to lithium solution (Li). In this fibre, voltage-clamped at -70 mV, the average lifetime of endplate channels (τ_n), calculated from $\tau_n = 1/2\pi f_c$ (f_c = half power frequency) was 1.5 ms in sodium solution and 2.5 ms in lithium solution. The current flow through individual channels (γ_i), determined both from the current spectral density at low frequencies and from the variance of current noise, was found to be reduced in lithium solution. Using the measured null potential, γ_c was calculated from $\gamma_c = \gamma_i / (V_m - \epsilon_s)$. Results obtained in several experiments are shown in Table 1. It can be seen that lithium caused a significant reduction in γ_c from 26.7 pS to 17.7 pS and this probably explains the reduction in m.e.p.c. amplitude caused by lithium (Fig. 1).

In experiments in which sodium chloride was replaced with caesium chloride in the extracellular solution, m.e.p.cs were increased in amplitude and their time constant of

decay was reduced. The acetylcholine null potential in caesium solution was 0.1 ± 0.9 mV (measured in five fibres). From analysis of acetylcholine noise it could be shown that the increase in amplitude and reduction in the time constant of m.e.p.cs in caesium were associated with changes in endplate channel characteristics. In one fibre exposed first to sodium, then to caesium solution the average lifetime of endplate channels was reduced from 1.21 ms to 0.89 ms while endplate channel conductance increased from 28.2 to 35.0 pS (clamp potential -50 mV). In four fibres voltage-clamped at -50 mV in caesium solution, average endplate channel lifetime was 0.98 ± 0.05 ms and endplate channel conductance was 34.7 ± 2.1 pS from power spectra and 33.3 ± 2.6 pS from noise variance.

The results indicate that these cations which must be passing through open endplate channels to generate the endplate current, change the conductance and lifetime of the channels. The sequence of average channel conductances was $\text{Li} < \text{Na} < \text{Cs}$ and the conductance ratios were $0.7 : 1 : 1.3$. Null potentials also became more positive in accord with this sequence. It is interesting and perhaps significant that the sequence of mobilities of the ions in free solution is also $\text{Li} < \text{Na} < \text{Cs}$ with free solution mobility ratios¹⁰ of $0.77 : 1 : 1.56$ at 20°C . If the conductance of an endplate channel is determined by free-solution mobility of ions flowing through it, the channel may well be a relatively large, water filled pore. Of course, the similarity between the channel conductance, null potentials and mobility sequences may be only a coincidence. It could be that ions alter endplate channel conductance by directly affecting the structure that forms the channel and this explanation might apply also for the effects of the ions on endplate channel lifetime. The sequence of channel lifetimes was $\text{Li} > \text{Na} > \text{Cs}$ and the lifetime ratios were $1.4 : 1.0 : 0.7$. Interestingly, there is a reciprocal relationship between channel lifetime and conductance (at least with the three ions tested). This may also be coincidental and the changes in channel lifetime may reflect separate and independent effects of these ions on the mechanism that determines channel lifetime. Whatever the mechanism and

Fig. 2 Plots of normalised current spectral density $S(f)$ against frequency f (Hz) obtained from a fibre voltage-clamped at -70 mV in sodium solution (\bullet) and after 30 min in lithium solution (Δ). $S(f)$ was calculated at 4-Hz intervals from the ensemble average of spectra from 16 segments of noise containing 512 points sampled at 2 kHz (cut-off filter 800 Hz, 3dB down). The downward and upward error bars show 1 s.e.m. at 4 Hz for the Na and Li curves respectively. Points at frequencies above 8 Hz are a segment average of adjacent values of $S(f)$. The solid lines were obtained by least squares fits of the points to a single Lorentzian and the arrows denote the half-power frequencies (63 Hz in Li solution, 107 Hz in Na solution). Spectral densities were normalised for comparison. Asymptotic spectral densities were 0.18×10^{-21} A²s (lithium) and 0.32×10^{-21} A²s (sodium).

Table 1 The average lifetime (τ_n) and conductance (γ_g) of endplate channels in muscle fibres voltage-clamped at -50 mV in solutions containing 115 mM LiCl, NaCl or CsCl

Solution	Li	Na	Cs
n	7	7	4
τ_n (ms)	1.91 ± 0.07	1.38 ± 0.11	0.98 ± 0.05
γ_g (pS)	17.7 ± 1.8 (16.7 ± 1.5)	26.7 ± 0.80 (26.2 ± 1.1)	34.7 ± 2.1 (33.3 ± 2.6)

Results were obtained from power density spectra except for the values of γ_g in brackets which were calculated from noise variance. An average ± 1 s.e.m. was obtained from n experiments. (Temperature 20°C .)

sites of action of these permeant cations, it is clear that they have significant effects on endplate channels. An understanding of the cause of these effects should provide further information about processes that determine endplate channel lifetime and conductance.

Evidence for the Clara cell as a site of cytochrome P450-dependent mixed-function oxidase activity in lung

THE cellular localisation of pulmonary mixed-function oxidase (MFO) activity has aroused considerable interest, especially because of the increasing incidence of lung disease of environmental origin—including cancers—and the realisation that many chemical toxins and carcinogens require MFO-catalysed activation. The precise identification of pulmonary cellular populations possessing MFO activity has previously met with little success, however, probably because of the complexity and heterogeneity of the lung, which has been estimated to contain over 40 different specific cell types¹. In this communication I describe studies with the pulmonary toxin, 4-ipomeanol (1-[3-furyl]-4-hydroxypentanone)², which indicate that a highly reactive metabolite of this naturally occurring furan derivative is preferentially formed and covalently bound in pulmonary non-ciliated bronchiolar (Clara)³ cells, leading to their necrosis. Since previous studies⁴ have established that the toxic metabolite formed *in vivo* during cytochrome P450-dependent oxidative metabolism of 4-ipomeanol is formed *in situ* in the lung, and does not reach the lung by way of the circulation, the present results indicate that the Clara cell is a primary locus of P450-dependent MFO enzymes in lung.

Covalently bound 4-ipomeanol metabolite was visualised in the lung using an autoradiographic technique and Fig. 1 shows examples of the striking appearance of the autoradiograms. As indicated by the accumulations of black photographic granules,

Fig. 1 Representative autoradiograms from lungs of rats (Sprague-Dawley, male, 100–120 g), mice (NIH-GP, male, 20–25 g), and hamsters (Golden Syrian, male, 60–70 g) given toxic doses of radiolabelled 4-ipomeanol (20 mg kg^{-1} rat or 35 mg kg^{-1} mouse and hamster) intraperitoneally. Generally-labelled ^3H -4-ipomeanol (60 mCi mmol^{-1}) was prepared by catalytic ($\text{Rh}/\text{Al}_2\text{O}_3$) tritiation with tritiated water. $^5\text{-}^{14}\text{C}$ -ipomeanol (2 mCi mmol^{-1}) was prepared using $1\text{-}^{14}\text{C}$ -propylene oxide². The animals were killed using pentobarbital 2 or 16 h after receiving the toxin and the lungs fixed *in situ* by intratracheal perfusion with 3% glutaraldehyde buffered with 0.1 M sodium cacodylate. Lungs were removed, cut, washed and dehydrated using a standard ethanol gradient, followed by a final wash with propylene oxide. Radioactivity remaining in the tissue after this procedure represented only the covalently bound 4-ipomeanol metabolite and could not be removed by further washing with aqueous or organic solvents or by organic solvent extraction of samples solubilised in 1 N sodium hydroxide. Samples of the specimens were embedded in paraffin or Epon 812 resin. Sections of 4–5- μm thickness were cut from the paraffin blocks and mounted on glass slides, and 2- μm thick sections were cut from the Epon blocks and mounted similarly. The slides were dipped in fresh Kodak NTB-2 photographic emulsion and placed in the dark for 2 or 4 weeks for tritium or ^{14}C -labelled samples, respectively. The exposed slides were developed and stained with toluidine blue. Frames a, b, c and d are rat lungs, frame e is hamster lung, and frame f is mouse lung. NC (arrows) identify non-ciliated bronchiolar (Clara) cells, and C (arrows) identify ciliated bronchiolar cells. The lung specimens were taken from animals 2 h after dosing with the toxin. Specimens shown in a, b, c and e were embedded in paraffin, the others were embedded in Epon resin. Scale bars: a, b, 200 μm ; c, d, e, 40 μm ; f, 20 μm .

the covalently-bound 4-ipomeanol metabolite was heavily concentrated in the lining cells of the airways. Similar results were obtained with both tritium and ^{14}C -labelled 4-ipomeanol, indicating that the binding did indeed represent covalently-bound metabolite, as previous biochemical studies have indicated, and was not due to nonspecific tritium exchange or carbon incorporation. Comparison of frames a, b and c from animals receiving the ^{14}C -labelled toxin, with d, e, and f from animals receiving the tritiated toxin, however, illustrates that greater resolution can be obtained using the tritium derivative, especially combined with Epon embedding and thinner sectioning. For example, in c, where the ^{14}C derivative was used, there seems to be some specific, but not precisely definable, cellular labelling; in d, e and f, however, it is possible to distinguish between the several types of bronchiolar lining cells³ and to appreciate the cellular specificity of the labelling.

In all three animal species tested, the Clara cells³ of the small airways were specifically alkylated by 4-ipomeanol (Fig. 1 d, e, f). In addition, in other specimens taken from animals 16 h after dosing with the toxin, a striking necrosis of the Clara cells was seen, whereas the adjacent ciliated bronchiolar cells, and the other major

pulmonary parenchymal cells were not necrotic (Fig. 2). Electron microscopic studies have confirmed these findings. It thus seems that the Clara cell is a specific cellular target of 4-ipomeanol. It is likely that pathological features of 4-ipomeanol poisoning which have been described previously in cattle⁵ and in experimental animals⁴, including pulmonary oedema, congestion and haemorrhage, are not primary events, but instead represent secondary or tertiary pathological changes. 4-Ipomeanol may serve as a useful tool for the elucidation of pathophysiological events related to Clara cell damage as well as the normal physiological role of the Clara cell.

To determine whether metabolism of 4-ipomeanol was required to produce the tissue-bound radioactivity, animals were pretreated with piperonyl butoxide, an inhibitor of the metabolism of 4-ipomeanol by both hepatic and pulmonary mixed-function oxidases⁴, before administration of the radiolabelled toxin. Histological examination of the lungs from these animals revealed a striking decrease in covalently-bound radioactivity in the bronchiolar cells (Fig. 3a, b) and the total absence of bronchiolar necrosis (not shown), even though both the blood and the pulmonary concentrations of the unmetabolised toxin were markedly elevated by the pretreatment (Fig. 3c). This experiment further illustrates that a highly reactive metabolite of 4-ipomeanol, which binds covalently with the target cells and which can be localised by the technique described here, is responsible for the Clara cell necrosis.

In studies of the dose dependency of bronchiolar binding and necrosis by 4-ipomeanol, it was shown that the sensitivity to the toxin decreases as airway size increases. With minimally toxic doses, covalently-bound radioactivity was maximally concentrated in the smallest airways and the subsequent development of bronchiolar necrosis was restricted to those areas. As doses were increased, proportionately larger airways were also labelled and eventually showed bronchiolar cell necrosis. It is possible that the seemingly greater sensitivity of the smaller airways is related to the fact that the relative proportion of Clara cells to the less sensitive ciliated bronchiolar cells increases as airway size decreases³.

Fig. 2 a, Normal mouse bronchiole with well defined ciliated (C) and non-ciliated, or Clara (NC) cells. b, A typical pulmonary bronchiole from a mouse 16 h after i.p. administration of non-radiolabelled 4-ipomeanol (35 mg kg^{-1}). In b, the necrosis of Clara cells is apparent, and, although abnormal, ciliated cells still seem to be viable. Scale bars represent $40 \mu\text{m}$.

Previous attempts to localise pulmonary MFO *in vivo* have been inconclusive. Some investigators have suggested an alveolar cell locus⁶, and others have indicated that a bronchial cell localisation was likely⁷. One report indicated that pulmonary macrophages have little MFO activity⁸. Reid *et al.*⁹ found that bromobenzene, in addition to its toxic effects on the liver, also produces pulmonary bronchiolar necrosis that seems to be related to covalent binding to bronchioles of a reactive metabolite of the compound⁹. The reactive metabolite of bromobenzene, however, seems to be sufficiently stable to escape from its site of formation⁹. Thus, with this compound it was not possible to determine if the toxic metabolite binding to lung was formed in the liver or in the lung, or in both, and neither was it possible to determine the specific type of

Fig. 3 Effect of piperonyl butoxide pretreatment ($1,600 \text{ mg kg}^{-1}$, i.p. 1 h previously) on bronchiolar alkylation (a, and b) and on blood and pulmonary levels of covalently-bound (solid columns) and free 4-ipomeanol (open columns) (c) in the rat. All tissues were removed and processed 2 h after administration of the ^{14}C -labelled toxin (20 mg kg^{-1} , i.p.). Covalently-bound toxin was assayed as described in ref. 4; free 4-ipomeanol was isolated using procedures described in ref. 2 and quantitated by liquid scintillation counting. Data in frame c are means ($\pm \text{S.E.M.}$) from groups of seven animals each. A, Control rats; B, treated rats. Scale bars represent $40 \mu\text{m}$.

bronchiolar cell to which the metabolite was bound, and which type of cell eventually became necrotic.

The physiological role of the Clara cell is unknown. Some argue that it is a source of pulmonary surfactant, whereas others feel its primary role is as a participant in the 'mucociliary elevator'. Pulmonary anatomists, however, have speculated that based on morphological features the Clara cell is metabolically a very active cell, with secretory functions. It is known to be richly endowed with smooth endoplasmic reticulum (SER)³ and this may be significant in the light of the present investigations, as SER is associated with MFO-activity in other cells, such as hepatocytes¹⁰. It is also interesting that the covalently bound 4-ipomeanol observed in the present experiments is most heavily concentrated in the cytoplasmic cap of the Clara cells, which is also the principal location of the SER³; nuclear labelling is minimal (Fig. 1f).

In summary, these studies indicate the Clara cell is an important potential site of oxidative metabolism of xenobiotics in the lung. Pathological changes of Clara cells, such as necrosis, or neoplastic transformation, which are produced by MFO-activated chemicals may therefore be explainable on that basis. Moreover, since the Clara cell possesses enzymes required for metabolic activation of certain chemical carcinogens, it must be considered a prime candidate as a cell of origin for at least some bronchogenic cancers. In continuing studies we hope further to define the biochemical characteristics of normal Clara cells, and to compare these properties with those of pulmonary tumours. The identification of biochemical similarities within specific histological types of human bronchogenic carcinomas, may implicate specific cell(s) of origin, and could possibly have important therapeutic use. In a tissue of relatively heterogeneous cellular composition such as the lung, cell types with enzymes capable of activating specific carcinogens may give rise to tumour cell populations uniquely susceptible to cytotoxins activated by the same enzymes. The possible use of specific bronchiolar alkylating agents, with 4-ipomeanol as the

prototype, should be explored as a new approach to chemotherapy of bronchogenic cancer of the lung.

Identification of a membrane-embedded segment of the large polypeptide chain of (Na⁺, K⁺)ATPase

THE sodium pump or (Na⁺, K⁺)ATPase couples hydrolysis of ATP to the active transport of Na⁺ and K⁺ across the cell membrane. The firm association of the enzyme with the membrane allows its purification from the outer renal medulla by selective extraction of other membrane proteins using sodium dodecyl sulphate (SDS)¹. Two polypeptide components remain in the purified preparation of (Na⁺, K⁺)ATPase. A catalytic protein with molecular weight (MW) about 100,000 (100 K) which constitutes 60-70% of the total protein and a smaller sialoglycoprotein of unknown function^{2,3}. The arrangement of these proteins within the membrane is an important but poorly understood aspect of the Na pump structure. Presumably the catalytic regions of the enzyme are in contact with the aqueous phase at the membrane surface, while other portions of the protein are in intimate contact with the lipid and account for its firm anchorage. The lipid associated domains of the pump are of special interest because in addition to a purely structural role, they may also form parts of the ion conducting pathways. We have been able to identify presumptive intramembranous portions of the Na pump protein by labelling them covalently from within the membrane with 5-[¹²⁵I]-iodonaphthyl-1-azide (INA). This label is a very hydrophobic light-sensitive compound developed previously for this purpose and tested with other systems⁴⁻⁷. A segment(s) of approximate MW 12 K derived from the large polypeptide chain has been identified by combining the INA-labelling technique with extensive proteolysis of the membrane bound enzyme. Graded proteolysis of the labelled (Na⁺, K⁺)ATPase has also permitted an estimate of the position of this segment within the large chain.

In the dark INA is unreactive and partitions (> 98%) into membranes^{8,9}. Subsequent irradiation at 310 nm (ϵ 21,400) converts INA into a reactive nitrene which inserts covalently into the protein and lipid components of the (Na⁺, K⁺)ATPase preparation (Fig. 1a). The distribution of radioactivity between protein and lipid could be controlled by varying the concentration ratio of label to enzyme. At low INA-to-protein ratios (roughly 0.5 mol INA per mol of enzyme) the label was attached almost exclusively to the large chain (Fig. 1a). In this experiment inhibition of the (Na⁺, K⁺)ATPase activity was less than 10%. The sialoglycoprotein was barely labelled and less than 20% of the radioactivity was associated with the lipid. Evidence for a membrane-bound segment of the large

chain was obtained by extensive digestion of labelled (Na⁺, K⁺)ATPase with trypsin (Fig. 1b) or thermolysin (not shown). In either case radioactivity was transferred essentially quantitatively from the large chain to a fragment(s) of MW about 12 K. After the extensive proteolysis only 45-50% of the original protein remains in the membrane whereas less than 10% of the radioactivity could be released from the membrane by

Fig. 1 Labelling of (Na⁺, K⁺) dependent ATPase with 5-[¹²⁵I]-iodonaphthyl-1-azide and effect of extensive trypsinolysis of labelled membranes. 0.6 mg of (Na⁺, K⁺)ATPase prepared from pig kidney¹ (specific activity 32.2 IU per mg protein) was suspended in 1 ml of a medium containing histidine, 25 mM, pH 7.5; EDTA, 1 mM and NaCl 100 mM. 5-[¹²⁵I]-iodonaphthyl-1-azide (0.2-0.3 µg of material with SA 1-3 × 10⁸ c.p.m. per µmol INA) prepared by methods described in ref. 7, was added in the dark in 10 µl of ethanolic solution. The membranes plus label were incubated at 37 °C for 5 min in the dark to allow full partitioning of the INA into the membranes. The suspension was then irradiated for 2 min with light mainly of wavelengths 313 and 365 nm produced by a mercury lamp HB200. The mercury lines below 300 and above 400 nm were excluded by passing the light through a Corning 7-60 band pass filter and Schott WG 305 cut off filter. After irradiation a small sample of the membranes was removed for measurement of (Na⁺, K⁺)ATPase activity¹⁰ and the rest was dialysed overnight at 0 °C against 1 l of solution containing histidine 25 mM, pH 7.5; EDTA 1 mM; bovine serum albumin 1 mg ml⁻¹. Radioactive diffusible byproducts of INA removed by this procedure amounted to about half of the total radioactivity added initially. For extensive proteolysis, portions of dialysed labelled enzyme containing 100 µg of protein were incubated for 1 h at 37 °C in 120 µl of medium containing imidazole 25 mM, pH 7.5, KCl 150 mM, CaCl₂, 1 mM, and trypsin 10 µg Sigma Type III. Then 1 ml of the medium (minus trypsin) was added to trypsinised and control membranes and these were centrifuged at 40,000 r.p.m. for 1 h in a Beckman type 65 rotor. About 10% of the total radioactivity was found in the supernatant, but there was no significant difference between the control and trypsinised enzyme. The pellets were dissolved in 100 µl SDS 2%, mercaptoethanol 1% and the dissolved material electrophoresed on polyacrylamide gels in SDS essentially as described in ref. 10. After staining with Coomassie blue and destaining in methanol acetic acid (see ref. 10) which also removed excess radioactive byproducts, the gels were cut into slices 1 mm thick, and the ¹²⁵I counted. The figure shows the distribution of radioactivity and position of Coomassie blue staining bands in duplicate gels. The arrows and letter M mark the tracking dye front. a, Control; b, following extensive trypsin digestion.

centrifugation. The large polypeptide chain disappeared and peptides with MW 58 K, 23 K, 20 K and 17 K staining with Coomassie blue were observed; staining in the region containing the radioactivity was weak or absent (see Fig. 1). The specificities of trypsin and thermolysin are very different and so it is quite likely that undigested peptides are protected from complete proteolysis by their association with the lipids.

After exposure of the enzyme at a much higher concentration of INA (namely 25–50 mol INA per mol of enzyme) the lipids became labelled to a level 6–8-fold greater than the protein and incorporation was also seen in the glycoprotein. In these conditions the $(\text{Na}^+, \text{K}^+)\text{ATPase}$ activity was almost completely inhibited and radioactivity equivalent to roughly one molecule of INA was incorporated into the large chain per mol of enzyme. Exhaustive trypsinisation of these membranes resulted in essentially the same pattern of the label distribution as shown in Fig. 1b.

Fig. 2 Distribution of radioactivity in fragments produced by controlled trypsinolysis in K^+ medium of INA labelled $(\text{Na}^+, \text{K}^+)\text{ATPase}$. $(\text{Na}^+, \text{K}^+)\text{ATPase}$ was labelled and dialysed as in Fig. 1. Aliquots containing 50–75 μg were incubated with trypsin at 37°C in a total volume of 0.5 ml in the following conditions: trypsin $\sim 3 \mu\text{g}$; KCl , 150 mM; imidazole 17 mM, pH 7.5; CaCl_2 , 1 mM. In b, CaCl_2 was absent and sample e contained 10 μg of trypsin. Trypsin inhibitor (0.5 ml of $20 \mu\text{g ml}^{-1}$) was added to the control sample (a) before addition of trypsin, and to the other samples after incubation with trypsin for the following times: b, 10 min; c, 15 min; d, 40 min and e, 60 min. The samples were then taken through the same steps as in Fig. 1. In these experiments the gels were run for 8–9 cm to facilitate observation of intermediate radioactive peaks. The lipids have migrated out of the gel into the lower bathing solution. Units of radioactivity have been normalised to account for variations in the total amount of protein applied to the gels in the different samples.

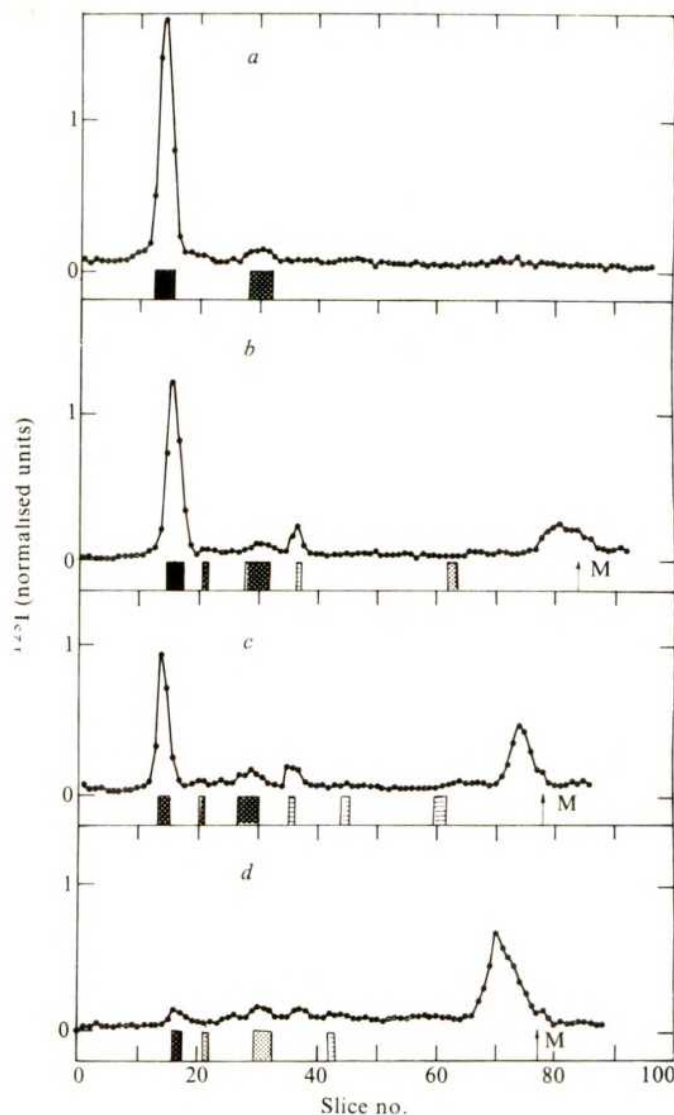

Fig. 3 Distribution of radioactivity in fragments produced by controlled trypsinolysis in a Na^+ medium of INA labelled $(\text{Na}^+, \text{K}^+)\text{ATPase}$. $(\text{Na}^+, \text{K}^+)\text{ATPase}$ was labelled and dialysed as in Fig. 1. Aliquots containing 50–75 μg were incubated with trypsin at 37°C in a total volume of 0.5 ml in the following conditions: trypsin, 3 μg ; NaCl , 150 mM and imidazole 17 mM, pH 7.5. Sample e also contained CaCl_2 1 mM. 0.5 ml of trypsin inhibitor $20 \mu\text{g ml}^{-1}$ was added to the control a before addition of trypsin and to the other samples after the following incubation times; b, 20 min; c, 40 min and d, 60 min. All other procedures were as in Figs 1 and 2.

The preferential insertion into the large chain at low concentrations of INA and inhibition of the $(\text{Na}^+, \text{K}^+)\text{ATPase}$ could imply contrary to expectation, that the label binds specifically to catalytic areas of the protein. Such areas are often hydrophobic clefts in enzyme surfaces. This possibility is unlikely for the following reasons. All catalytic functions are destroyed by relatively limited proteolysis^{8,9} but, as seen above, exhaustive proteolysis did not release the label. Furthermore, binding to the ATP binding site of a fluorescent ATP analogue, formycin triphosphate¹¹ was unaffected by incorporation of sufficient idonaphthyl groups to inhibit activity by 70%, and ATP did not alter incorporation of label into the protein when it was present during irradiation (not shown). We did not study the mechanism of inhibition any further. But, the observation that INA does not interfere with ATP binding is compatible with the notion that it may inhibit catalysis by perturbing protein–lipid interactions, since it has been shown that ATP binding is unaffected after inactivation of $(\text{Na}^+, \text{K}^+)\text{ATPase}$ by complete delipidation¹².

We have examined labelling of the large protein in Na^+ - or K^+ -containing media. The enzyme adopts specific Na^+ - or K^+ -dependent conformations^{8,12-14} and so it was interesting to ask whether these different states are accompanied by a change in accessibility of the protein to INA in the bilayer. In six separate experiments with different concentration ratios of label to protein we observed 10–25% greater incorporation into the large chain in the presence of KCl than with NaCl. This may mean that the conformational change following binding of K^+ leads to an altered relationship of protein to lipid.

In attempts to localise the 12 K fragment we exploited the fact that major fragments of the large chain can be produced by controlled tryptic cleavage in the presence of NaCl or KCl because the conformational response of the protein to cation binding is reflected in exposure of different bonds to tryptic attack^{8,9}. Thus, fragments with MW 58 K and 46 K were formed by primary cleavage of the large chain in presence of KCl. A fragment of 78 K was seen after digestion in the presence of NaCl. The distribution of INA in protein fragments generated by controlled trypsinolysis of enzyme labelled at low INA concentrations is shown in Figs 2 and 3. These results show clearly that the binding of INA does not prevent the conformational response of the large chain to Na^+ and K^+ . In the presence of KCl (Fig. 2) most of the radioactivity of the large chain was transferred to the 46 K fragment, but some labelling of the 58 K fragment was also seen. Comparison of radioactivity in the peaks with the content of protein obtained from absorbance scans of the gels showed that about 80% of the label was transferred to the 46 K fragment and only 20% to the 58 K fragment. Subsequently a 36 K fragment and the terminal 12 K peptide appear. The 46 K and the 36 K fragments therefore include segments which are embedded in the bilayer. The low concentration of label in the 58 K fragment may be due either to labelling of different parts of the large chain or to variation of the position of the tryptic split within the large chains in the preparation.

In the presence of NaCl (Fig. 3), the distribution of label was much more distinct. The 78 K fragment was completely devoid of radioactivity and the terminal 12 K fragment seems to arise almost by primary cleavage of the large chain. A minor fraction of the label, at most 2%, was found in a 37 K fragment. This implies that the radioactive 12 K segment or segments are localised near one end of the large chains which give rise to the 78 K fragment in the presence of NaCl.

Our results support previous evidence that iodonaphthylazide acts as a hydrophobic probe which labels membrane proteins from within the bilayer. The selectivity of the label for a small segment of the large peptide does not imply that other regions of the protein are not embedded in the membrane, for the labelled segment may hinder access of the label to other areas of the large peptide or indeed to the glycoprotein component. Preferential binding to this segment, or kinetic factors could explain the discrimination against unlabelled regions of protein and lipid side chains. Our work illustrates that combining specific labelling from within the lipid core with proteolytic digestion at the membrane surface may be an important tool for identifying segments of membrane proteins in intimate contact with the lipids.

We thank Dr T. Bercovici for ¹²⁵I-INA and Mrs Rivka Goldshlegger and Annie Sloth for excellent technical assistance. P.L.J. was a recipient of a short-term fellowship from EMBO.

Synthesis of haemoglobin Wayne in erythroid cells

HETEROZYGOTES for haemoglobin (Hb) Wayne possess two minor haemoglobin components that migrate more rapidly than HbA on electrophoresis at pH 8.6. Each of the minor haemoglobin components contains an abnormal α chain in which the carboxyl-terminal tripeptide sequence, Lys-Tyr-Arg, has been replaced by an octapeptide¹. The slower of the two components, henceforth designated Wayne-Asn, has the following octapeptide sequence: Asn-Thr-Val-Lys-Leu-Glu-Pro-Arg, whereas the faster one (Wayne-Asp) has exactly the same sequence except that asparagine at position 139 is replaced by aspartic acid. (These components, formerly designated¹ Wayne-1 and Wayne-2, respectively, have been renamed for clarity.) This is the first variant described in which deamidation of the gene product is believed to occur. The purpose of this study was to demonstrate the proposed deamidation and to explain another interesting feature of the Hb Wayne phenotype in heterozygotes: namely, the presence of the variant haemoglobins in markedly reduced quantities relative to HbA (3% and 4%, respectively, for Hb Wayne-Asn and Hb Wayne-Asp).

Peripheral blood red cells from two heterozygotes with Hb Wayne and bone marrow cells from one of them were incubated for 60 min in the presence of ³H-labelled leucine. A fraction of the labelled haemolysates was converted into globin immediately by precipitation in acid-acetone. The α/β ratios obtained, based on total counts and the specific activities, indicate that the synthesis of α chains is equal to that of the β chains in the peripheral blood and bone marrow (balanced synthesis). Moreover, a free α chain peak could not be demonstrated after chromatography of the haemolysates on Sephadex G-100 gel filtration columns.

In order to compare more precisely the specific activities of the various α chains (Table 1), it was necessary to first purify the haemoglobins in the labelled haemolysates by column chromatography of the haemolysates on carboxymethyl cellulose². This was followed by preparative isoelectric focusing of the peaks containing the Hb Wayne fractions using LKB columns and finally globin chain separation³. The Wayne chain fractions obtained were shown to be free of contamination by peptide chromatography of tryptic digests.

In the peripheral blood incubations the amount of radioactivity corresponding to the α^{Wayne} chains was less than 11% of the total α chain radioactivity (Table 1). The corresponding value in the bone marrow was 11.4%. These figures were considerably lower than the 25% expected on the basis of the two loci believed to be present for α chains. The $\alpha^{\text{Wayne-Asn}}/\alpha^{\text{A}}$ specific activity ratio was 2.40 to 2.46 in the peripheral blood and 3.1 in the bone marrow, suggesting instability of the $\alpha^{\text{Wayne-Asn}}$ chains. In both peripheral blood and bone marrow, the specific activity of the $\alpha^{\text{Wayne-Asp}}$ chains was lower than that of the $\alpha^{\text{Wayne-Asn}}$ chains (Table 1). Time course experiments using peripheral blood showed no change in the $\alpha^{\text{Wayne-Asn}}/\alpha^{\text{Wayne-Asp}}$ ratio from 4 min to 3.5 h (not shown).

In order to evaluate the difference in labelling of the two types of variant α chains a pulse-chase experiment was performed. Peripheral blood red cells from a heterozygote were incubated in the presence of ³H-leucine for 15 min (pulse) after which they were washed and a portion was immediately frozen. The remaining cells

Table 1 Incorporation of ^3H -leucine into α and β chains following incubation of red cells for 60 min

	α/β ratios of globin from crude haemolysates	Specific activity	Radioactivity of purified α chains					
			Specific activity (c.p.m. per mg)		% Of total α chain radioactivity			
	Total counts		$\alpha^{\text{Wayne-Asn}}$	$\alpha^{\text{Wayne-Asp}}$	α^{A}	$\alpha^{\text{Wayne-Asn}}$	$\alpha^{\text{Wayne-Asp}}$	α^{A}
Peripheral blood (WS)	0.97	0.94	644	115	262	8.36	1.80	89.84
Peripheral blood (GS)	1.04	0.96	968	202	403	6.96	1.95	91.09
Bone marrow	1.12	0.91	40,039	837	12,880	11.16	0.27	88.57

A fraction of the crude haemolysates was converted to globin immediately by precipitation in acid acetone. The globin obtained was chromatographed on columns of Sephadex G-100 in 20% HCOOH^{15} . After chromatography globin fractions were recovered by freeze drying. Another fraction of the haemolysate was used for purification of the various haemoglobin components for accurate determination of radioactivity in the α^{Wayne} chains. Globin chain separation was carried out according to Clegg *et al.*³ Aliquots of 1 ml of each fraction were added to 10 ml Instagel (Packard) and counted by scintillation spectroscopy. The total radioactivity under each peak was summated. The various chain components were then pooled, desalted on Biogel P2 columns equilibrated with 0.5% formic acid, and lyophilised. The chains were re-dissolved in distilled water and the protein concentration determined by the Lowry method²⁹.

were reincubated in a medium containing unlabelled leucine (chase) for 1, 4 and 6 h. The specific activities of the α^{A} and β chains remained unchanged during the chase period as did that of the $\alpha^{\text{Wayne-Asn}}$ and $\alpha^{\text{Wayne-Asp}}$ chains (Table 2), suggesting that during the short period of the chase no detectable conversion or degradation of the abnormal chains relative to each other or to α^{A} occurs. If deamidation is a slow process, then a greater proportion of Hb Wayne-Asn relative to Hb Wayne-Asp should be present in reticulocytes when compared with the more mature red cells. A reticulocyte fraction was prepared from the peripheral blood of a heterozygote by means of a discontinuous Ficoll density gradient⁴. Isoelectric focusing in polyacrylamide gels of the reticulocyte haemolysate revealed a markedly decreased proportion of Hb Wayne-Asp when compared to the haemolysate prepared from unfractionated peripheral blood. Moreover, the proportion of Hb Wayne-Asn in reticulocytes was approximately twice as much as in peripheral blood (Fig. 1).

The above data support the hypothesis that $\alpha^{\text{Wayne-Asn}}$ chains are synthesised initially and subsequently converted to $\alpha^{\text{Wayne-Asp}}$ chains. Robinson and others⁵⁻⁸ have shown that specific glutamyl and asparaginyl residues have characteristic rates of deamidation that are determined by the nature of neighbouring amino acid residues in both the primary and tertiary structures. The discovery of Hb Providence, a β chain variant present as two components, one having asparagine instead of lysine at position 82 and the other having aspartic acid at the same position, indicates that deamidation is not unique to Hb Wayne⁹⁻¹⁰. It is also possible that Hb J-Singapore¹¹ is not a double substitution variant but a neutral substitution at $\alpha^{79} \text{Ala} \rightarrow \text{Gly}$ followed by deamidation at α^{78} to yield aspartic acid¹².

It is interesting to note that $\alpha^{\text{Wayne-Asp}}$ chains account for a higher proportion of the total α -chain radioactivity in peripheral blood than in bone marrow (Table 1); the $\alpha^{\text{Wayne-Asn}}/\alpha^{\text{Wayne-Asp}}$ ratio was 0.5 in the former and 0.06 in the latter. A possible explanation for all of these findings is that the asparagine at residue 139 of $\alpha^{\text{Wayne-Asn}}$ forms a cyclic imide, as proposed by Bornstein¹³, while the chains are in the nascent chain or monomer conformation. While in this conformation the cyclic imide is rapidly hydrolysed to the aspartyl form. Once the $\alpha^{\text{Wayne-Asn}}$ chain is incorporated into the Hb Wayne tetramer further cyclisation is blocked by steric

hindrance but those cyclised chains that had formed are hydrolysed very slowly. In the bone marrow any $\alpha^{\text{Wayne-Asp}}$ monomer chains produced by deamidation of $\alpha^{\text{Wayne-Asn}}$ monomers might be rapidly degraded by proteolytic enzymes that are not active in mature erythrocytes^{14,15}.

Fig. 1 Isoelectric focusing in polyacrylamide gels of peripheral blood haemolysate (left) and reticulocyte haemolysate (right). The densitometric tracings were made on unstained gels at 410 nm using a Gilford recording spectrophotometer.

Table 2 α Chain specific activities during a pulse chase experiment

Incubation time	Specific activity (c.p.m. per mg)		$\alpha^{\text{Wayne-Asp}}/\alpha^{\text{A}}$	$\alpha^{\text{Wayne-Asp}}/\alpha^{\text{A}}$	$\alpha^{\text{Wayne-Asn}}/\alpha^{\text{Wayne-Asp}}$
	$\alpha^{\text{Wayne-Asn}}$	$\alpha^{\text{Wayne-Asp}}$			
15 min pulse	1,510	275	1.80	0.33	5.49
1 h chase	1,631	286	1.84	0.32	5.70
4 h chase	1,572	283	1.73	0.31	5.55
6 h chase	1,590	269	1.79	0.30	5.91

The presence of Hbs Wayne as minor components is shared by Hbs Constant Spring¹⁶⁻¹⁸, Koya Dora¹⁹, Icaria²⁰ and Seal Rock²¹, other variants characterised by elongated chains. Because the α_{Wayne} chains comprise only 11% of the total α chains synthesised during the period of incubation, instability of the chains does not fully account for the low proportion of Hb Wayne. A delay in translation of the α_{Wayne} chains as a result of a deficiency of tRNA for one or more of the amino acids corresponding to the abnormal sequence cannot be excluded, although such a delay has not been found in any of the abnormal haemoglobins that are present in reduced amount and that have been studied²²⁻²⁵, including Hb Constant Spring¹⁶. Perturbation of termination of translation *per se* seems also an unlikely explanation since the synthesis of Hb Cranston, a frameshift mutant of the β chain, is not so severely impaired²⁶. Yet another possible explanation, that the mRNA has been rendered unstable by the deletion responsible for the frame shift, has been excluded by the demonstration that no more Hb Wayne components are synthesised in bone marrow than in peripheral reticulocytes.

The expectation that an α -chain mutant would direct the synthesis of 25% of the α -chain mRNA is based on the unproven assumption that there are two loci that are equally active in directing α -chain synthesis. This assumption is partly based on the fact that individuals heterozygous for Hbs J-Buda and G-Pest²⁷ possess close to 25% of these variants, along with approximately 50% of Hb A, as well as the fact that a large number of other α -chain structural mutants comprise 20-25% of the haemoglobin of heterozygotes. Haemoglobin synthesis studies have not been performed on most of these variants. Consequently their true rate of synthesis is not known. Therefore, the reduced production of the Constant Spring and α_{Wayne} chains could also be explained on the basis of multiple α -chain loci that are not equally active in α -chain synthesis. Such a hypothesis has been invoked to explain a greater than expected amount of Hb J-Mexico in heterozygotes²⁸. It is possible to envision one major locus, another of intermediate activity, and a third locus accounting for only a minor proportion of alpha chains. The mutation in α_{Wayne} would correspond to the intermediate locus and that of $\alpha_{\text{Constant Spring}}$ would correspond to the minor locus. A complete understanding of these complex abnormalities requires study of additional informative mutants.

Red cell charge is not a function of cell age

REPORTS^{1,2} that the oldest circulating human erythrocytes have an electrophoretic mobility up to 30% lower than the youngest cells have been widely accepted, particularly since such findings suggest a plausible mechanism for the removal of the oldest cells from circulation. For those studies^{1,2} the red cells were separated on the basis of age by using the accepted relationship that older cells are denser on the average than younger cells. We report here that electrophoretic mobility studies conducted independently by conventional electrophoresis, streak width measurements and electrophoretic light scattering have shown the mobilities to be the same for red cell fractions of differing density and hence age *in vivo*. These data suggest that hypotheses which invoke a role for decreasing surface charge density in the mechanism of senescent red cell recognition *in vivo* are unsound.

The non-random nature of the red cell elimination process has led to suggestions that membrane determinants such as red cell surface charge³ and/or antibody binding to the cell surface⁴ may provide specificity as a result of age-dependent alterations which enhance cell adhesion to phagocytic cells.

The observation that various sialoglycoproteins are rapidly eliminated from the blood following removal of their sialic acid⁵ has prompted considerable speculation on the role of sialic acid loss in the ageing and elimination of red cells^{6,7}. In some instances, normal lifespans have been observed for sialic acid deficient red cells⁸⁻¹⁰. But, the sialic acid content of old (dense) red cells is lower than young (less dense) cells¹¹⁻¹³. As the major source of negative surface charge on human red cells is the carboxyl group of membrane-bound *N*-acetylneuraminic acid¹⁴, an age-related decrease in electrophoretic mobility^{1,2} is consistent with a net loss of sialic acid per unit of membrane surface area.

Fig. 1 Electrophoretic light scattering spectra¹⁹ for least dense (top) and most dense (bottom) human red cell subpopulations at 25 °C in 0.0145 M NaCl-4.5% w/v sorbitol-0.007 M bis-Tris buffer at pH 7.3. The top and bottom fractions each representing ~2% of the whole population were obtained by centrifugation of the cells in their own plasma for 30 min, 140,000g at 4 °C followed by three washes in the electrophoresis buffer. The mean Doppler shift for both spectra is 39.5 Hz, which corresponds to an electrophoretic mobility of $2.75 \pm 0.05 \mu\text{m s}^{-1} \text{ V}^{-1} \text{ cm}$ after a correction for electro-osmosis (9.8 Hz). Experimental parameters were: scattering angle, 14.9 °; laser wavelength, 514.5 nm; electric field, 16.2 V cm⁻¹ and frequency resolution of ~0.03 Hz. In these conditions a 20% difference in mobility would produce a difference in shift frequency of ~6 Hz. The spectra shown for the subpopulations were indistinguishable from that of the whole population (not shown).

Table 1 Streak width and aspartate aminotransferase activities¹⁷ for whole red cell populations and extreme density fractions representing 2–7% of the whole populations

Sample no.	Aspartate aminotransferase (IU per 10 ¹⁰ RBC)			Unfractionated	Electrophoretic streak width (mm)		
	Unfractionated	Top	Bottom		Top	Bottom	Top and bottom
1	0.95	1.66	0.40	0.79	1.27	1.01	0.88
2	1.88	7.15	0.87	0.61	0.56	0.64	0.66
3	2.96	5.22	0.95	0.84	1.00	0.97	1.16
4	0.87	2.12	0.58	0.57	0.68	0.62	0.74
5	1.53	1.26	0.49	0.62	0.64	0.67	0.60
5a	1.53	1.13	0.58	0.62	0.62	0.64	0.62
6	1.20	1.79	0.89	0.79	0.98	0.81	1.07
6a	1.20	1.60	1.02	0.79	0.78	0.79	0.80

Samples 1, 4, 5 and 6 were obtained from adults, samples 2 and 3 from the umbilical cord of infants at birth. All samples were fractionated by repeated centrifugation for 30 min at 2000g on phthalate ester mixtures¹⁸ except for samples 5a and 6a which were obtained by ultracentrifugation at 50,000g, 20 °C for 2 h. Cell suspensions (2% v/v) in pH 7.4, 16.5 mM Tris-acetate buffer containing 5% sucrose were electrophoresed at 21 °C, 80 V cm⁻¹. Streak widths are to be compared with the 13.8 mm total distance of migration for a mobility of 2.3 $\mu\text{m s}^{-1} \text{V}^{-1} \text{cm}$ RBC, red blood cell.

To detect any significant dispersity in electrophoretic mobility which accompanies changes in density and *in vivo* ageing of red cells, the extreme ends of the red cell density distribution were examined for evidence of differences in electrophoretic mobility. Using various red cell density fractionation procedures, studies conducted independently in our three laboratories with different instrumentation and conditions do not show any experimentally significant electrophoretic mobility differences for the extreme red cell subpopulations.

Electrophoresis of erythrocyte fractions by the continuous-flow streak deflection method¹⁵ was carried out in the conditions previously reported¹⁶ using the Kolin endless belt electrophoresis apparatus. If present, heterogeneity in electrophoretic mobility of cell populations is evidenced by progressive sample band broadening on passage through the electrical field of the instrument and by actual band splitting for samples with multimodal mobility distributions. Examination of the banding behaviour for whole and density-fractionated human red cell populations (Table 1) gave no indication of electrophoretic inhomogeneity. The maximum observed bandwidths were consistent with about a 5% range in electrophoretic mobility for mixtures of cells made from the density extremes. The band or streak width expected on the basis of Yaari's data² for 'top' and 'bottom' cell mixtures is about five times the observed value. Furthermore the band should have shown signs of observable splitting as the run progressed. Marked

differences in red cell aspartate aminotransferase activity between the fractions indicated that significant cell separation according to cell age had been achieved¹⁷.

Electrophoretic light scattering spectra (Fig. 1) for 'top' and 'bottom' fractions of red cells obtained by ultracentrifugation also failed to show significant differences between the mean mobilities or the mobility distributions.

Analytical electrophoretic mobility data for samples of top and bottom cell populations obtained by two different density fractionation techniques also showed no differences either at high or low ionic strength (Table 2). Extreme subpopulations representing as little as 1% (not shown) were not found to differ.

In each of the described electrophoresis systems the expected mobility differences² for red cells from the extremes of the density distribution should have been detected with ease. We conclude from the lack of any clear indications of mobility heterogeneity in these studies which involved different density separation and electrophoretic monitoring techniques that no measurable differences in mobility are correlated with red cell density through the central ~95% of the density distribution. This is in contrast to the observations of Yaari² which showed electrophoretic mobility to be a monotonic function of cell density through this range.

Electrophoretic mobility is recognised as a measure of net surface charge density²³. A constant electrophoretic mobility for red cells of different densities implies that the effective net number

Whole blood samples were collected by venipuncture from four adult subjects. Fractions were washed once in 2–4 volumes of autologous plasma, three times in > 20 volumes of pH 7.4, 0.144 M NaCl–0.01 M potassium phosphate (PBS). Mean cell haemoglobin concentration (MCHC) was calculated from haemoglobin assayed as cyanmethaemoglobin and microhaematocrit values after centrifugation for 5 min at 15,000g. *N*-acetylneuraminic acid (NANA) was assayed in supernatants²¹ after incubation of $\sim 2 \times 10^9$ RBC per ml in PBS plus ~ 100 Behringwerke units of *Vibrio cholera* neuraminidase for 1 h at 37 °C. Aspartate aminotransferase (glutamic oxaloacetic transaminase, GOT) was assayed spectrophotometrically²² and activity is expressed in international units (IU) where one unit represents the conversion of 1 μmol of NADH to NAD⁺ in 1 min at 25 °C. Mobilities were measured at 25 °C in cylindrical chambers equipped with Ag/AgCl electrodes²³ or Pt electrodes²⁴, and operated at voltage gradients < 5 V cm⁻¹ and currents < 3 mA to minimise joule heating. Mean mobilities and standard deviations are given for the number of cells in parentheses. The two ionic strength media listed were buffered to pH 7.2 \pm 0.2 with NaHCO₃ and 0.03 M NaCl contained 4.0% (w/v) sorbitol to maintain medium tonicity.

of negative charges per unit area of membrane surface as observed by electrophoresis remains constant even though the total number of charge groups, such as sialic acid, on the cell surface may be decreased as, for example, by membrane loss.

Ion-induced changes in head group conformation of lecithin bilayers

THE structure and orientation of the phosphocholine polar group in lecithin-containing membranes has been discussed extensively. Studies of egg-yolk lecithin and 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC), using neutron diffraction and ^1H and ^{31}P nuclear magnetic resonance (NMR), have led to the conclusion that the phosphocholine dipole is orientated parallel to the membrane surface¹⁻⁴. On the other hand, ^1H and ^{31}P NMR spectra of sonicated DPPC vesicles in the presence of trivalent ions suggested that the choline group is extended approximately perpendicular⁵ or folded parallel⁶ to the bilayer surface. We have, therefore, repeated our previous ^1H and ^{31}P NMR measurements in the presence of trivalent ions and report here that the addition of these shift reagents induces large changes in the spectral parameters, that is, the ^1H quadrupole splittings and the ^{31}P chemical shift anisotropy. These observations can only be interpreted in terms of specific ion-induced changes in the choline head group conformation of DPPC.

Typical spectral changes observed on addition of EuCl_3 , LaCl_3 and $\text{K}_3\text{Fe}(\text{CN})_6$ to unsonicated dispersions of DPPC are shown in Figs 1-3. The observed changes cannot

Fig. 1 Phosphorus-31 NMR spectra of unsonicated multibilayers of DPPC complexed with trivalent ions at 48 °C. *a*, No ions; *b*, $\text{Fe}(\text{CN})_6^{3-}$; *c*, $\text{La}(\text{III})$; *d*, $\text{Eu}(\text{III})$. Solutions of $\text{K}_3\text{Fe}(\text{CN})_6$, LaCl_3 , and EuCl_3 were prepared as described in ref. 5. Approximately 200 mg of DPPC were mixed with 0.5 M ion solutions to yield a final concentration of 50 wt % H_2O and a DPPC to ion mole ratio of 2.7. The samples were then sealed in glass ampoules and placed in 10-mm NMR tubes. The NMR spectra were obtained in the pulsed Fourier transform mode at 36.4 MHz using a Bruker HX-90 spectrometer/B-NC-12 data system equipped with a deuterium lock and home-built quadrature phase detection. Approximately 5,000 free induction decays were averaged to obtain these spectra. A proton-decoupling field of 10 W tuned to the CH_2 resonance of the choline head group moiety was applied. The chemical shifts are relative to 85% orthophosphoric acid. The residual chemical shift anisotropy ($\Delta\sigma$) is given approximately by the separation between the edges of the powder spectra.

be ascribed to general ionic strength effects, since no spectral changes are apparent in control studies using NaCl. Different patterns of spectral behaviour are observed at all of the head group segments studied. Binding of $\text{La}(\text{III})$ or $\text{Fe}(\text{CN})_6^{3-}$ has little effect on the shape of the ^{31}P NMR spectra. But on addition of $\text{Eu}(\text{III})$ a large chemical shift is observed which is accompanied by an apparent reversal in the sign of the chemical shift anisotropy. The effects of ion binding on the quadrupole splittings of the $^1\text{NCH}_2\text{CD}_2$ and $^1\text{NCD}_2\text{CH}_2$ segments (the α and β positions, respectively) tend to be generally in the same direction, but the magnitude of the observed changes is ion-specific. The observed quadrupole splitting at the α position is decreased, whereas that at the β position is increased on ion binding. Little change is apparent at the $(\text{CD}_3)_3\text{N}^+$ segment (data not shown). The data are summarised in Table 1.

The mole ratios of ion to phospholipid used in this work are higher than those used by Hauser *et al.*⁵, however, concentration dependence studies reveal significant effects at ion : phospholipid mole ratios as low as 1 : 10. In the case of $\text{Eu}(\text{III})$ binding, two components are seen in the ^{31}P NMR spectra in certain conditions—the predominant spectral component is shown in Fig. 1. It is also possible that there is more than one component on binding of $\text{La}(\text{III})$ or $\text{Fe}(\text{CN})_6^{3-}$, as the lack of a chemical shift in the ^{31}P NMR spectra upon binding of these ions would make it difficult to resolve components with similar chemical shift anisotropies.

Fig. 2 Deuterium NMR spectra of unsonicated multibilayers of $^+NCH_2CD_2$ -DPPC complexed with trivalent ions at 59 °C. *a*, No ions; *b*, $Fe(CN)_6^{3-}$; *c*, $La(III)$; *d*, $Eu(III)$. Selectively deuterated DPPC was prepared as described in ref. 3. The spectra were recorded at 13.8 MHz with a fluorine lock; otherwise the experimental conditions are identical to those described in the legend to Fig. 1. Approximately 6,000–10,000 free induction decays were averaged to obtain the spectra. The absolute value of the residual quadrupole splitting ($\Delta\nu$) is given by the separation between the two largest peaks in the powder-type spectra. Note that the spectra are recorded at different gains.

Since DPPC dispersions complexed with trivalent ions undergo phase transitions at temperatures near the gel to liquid crystalline phase transition of pure DPPC (ref. 7 and H. U. Gally, personal communication), it is unlikely that the bilayer structure is disrupted on binding of any of the ions used here. The static electric field gradient tensor of the 2H labels primarily reflects the electronic structure of the bonds containing these atoms and is not affected by ion binding to the phosphocholine groups. The observed changes in the residual quadrupole splitting must, therefore, be due to changes in the head group motion and conformation. The exact nature and extent of these conformational changes can only be determined from a quantitative analysis of the 2H and ^{31}P NMR data, which will not be pursued here. The interpretation of the ^{31}P NMR data is not unequivocal, as it is possible that the contact shift due to

$Eu(III)$ binding⁵ may be different for the different components of the chemical shielding tensor. In principle, this could account for the different ^{31}P NMR spectral changes associated with $Eu(III)$ and $La(III)$ binding and would be consistent with the similar 2H NMR spectral changes observed on binding of these ions. The binding of $Eu(III)$ and $La(III)$ to phospholipids is believed to be very similar³. An alternative explanation, however, is that the contact shift is similar or identical for all the principal components of the chemical shielding tensor, in which case the ^{31}P NMR spectral changes upon $Eu(III)$ binding would reflect changes in molecular motion at the phosphate segment. Further work, for example, determination of the ^{31}P static chemical shift tensor of DPPC complexed with shift reagents, is needed before a firm conclusion can be reached.

Fig. 3 Deuterium NMR spectra of unsonicated multibilayers of $^+NCD_2CH_2$ -DPPC complexed with trivalent ions at 59 °C. *a*, No ions; *b*, $Fe(CN)_6^{3-}$; *c*, $La(III)$; *d*, $Eu(III)$. Experimental conditions as in Figs 1 and 2.

The data presented here suggest that caution should be exercised in applying the results of NMR structural analysis using paramagnetic ions to phospholipid bilayers free of complexed ions. The observation of specific ion-induced changes is consistent with the idea that the phosphocholine group of DPPC is not in a fixed, rigid conformation^{3,4,8} and further suggests that structures deduced from data for binding of several ions^{5,6} may represent averages over several different conformations. These results are a direct demonstration of ion-induced changes in the head group conformation of phospholipids. Similar conclusions regarding lanthanide binding have been reached by Hauser *et al.* (manuscript in preparation). From a biological point of view, it will be interesting to see if divalent cations such as Ca^{2+} induce similar spectral changes and whether these changes can be quantitatively interpreted in terms of changes in head group conformation.

We thank Dr R. J. P. Williams for helpful comments. This work was supported by grant 3.008.76 from the Swiss National Science Foundation (J.S.) and a postdoctoral fellowship from the U.S. National Institute of General Medical Sciences (M.F.B.).

Table 1 Effect of trivalent ions on 2H quadrupole splittings ($\Delta\nu$) and ^{31}P chemical shift anisotropy ($\Delta\sigma$) of the phosphocholine group of DPPC

Segment	No. of ions added	$Eu(III)$ $\Delta\sigma$ (p.p.m.)	$La(III)$	$Fe(CN)_6^{3-}$
PO_4^-	-44	+44	-54	-51
		$ \Delta\nu $ (kHz)		
$^+NCH_2CD_2OP$	5.9	~ 1	~ 0	3.9
$^+NCD_2CH_2OP$	4.4	7.2	6.9	5.1

Ion solutions were prepared as described in ref. 5. $[DPPC]/[ion] = 2.7-3.0$. $[H_2O] = 50 \pm 0.3\%$ by weight. Temperature, 59 °C.

Replication of linear adenovirus DNA is not hairpin-primed

THE mechanism of replication of the 5' ends of linear DNA chromosomes remains unclear^{1,2}, as the known DNA polymerases, which act in the 5' to 3' direction, require a free 3'-OH as a primer for chain elongation. If a short ribonucleotide sequence primed DNA synthesis, its subsequent removal would leave no primer for gap fill synthesis at the 5' end. Most linear bacteriophage DNA molecules therefore have terminal repeats or single stranded complementary ends, which allow formation of circular or concatemeric replication intermediates¹. Several interesting models have been proposed to explain replication of the 5' ends of eukaryote chromosomes and linear DNA molecules which cannot circularise. Cavalier-Smith³ proposed that chromosome ends can form self-complementary hairpin loops,

allowing the parental 3' end to act as a primer for DNA polymerase, followed by endonuclease action and repair synthesis. This model has been modified by Bateman⁴ and Tattersall and Ward⁵ have extended it to propose a rolling hairpin model for the replication of parvovirus and linear chromosomal DNA. There is now considerable evidence for hairpin priming of replication of the DNA of minute virus of mice (MVM) and adeno-associated virus (AAV)^{6–7}, and hairpin priming may well be a general mechanism for replication of linear DNA molecules that are unable to circularise or form concatemers^{3,5,7}. Roberts⁸ and Wu *et al.*⁹ have proposed a hairpin-primed model for replication of adenovirus DNA, which is summarised in Fig. 1. We present evidence here which is not consistent with a hairpin-primed model for replication of adenovirus DNA.

Human adenovirus DNA is a linear duplex and has ends with properties consistent with an inverted terminal repetition that is not palindromic¹⁰. J. R. Arrand and R. J. Roberts (manuscript in preparation) have sequenced the inverted terminal repetition in adenovirus type 2 and have shown it to be a unique, non-palindromic sequence of 102 base pairs (sequence a b c in Fig. 1) with an unpaired modified 5' terminal deoxycytidine. Covalently attached to each 5' end of the DNA is a 55,000 molecular weight (MW) protein¹¹, possibly linked to the DNA by the unpaired deoxycytidine residue. The DNA replicates by a strand displacement mechanism and the origins and termini of DNA replication are at the molecular ends of the chromosome^{12–14}.

One consequence of the hairpin-primed model (Fig. 1) is that with each round of replication, the terminal sequence must be inverted, resulting in four types of molecules differing in the order of the terminal sequences. As the adenovirus termini are not palindromic, the first round of replication products would have terminal repeats of two types and 50% of intracellular viral DNA should therefore anneal

Fig. 1 Model for self-primed initiation of adenovirus DNA replication by a hairpin mechanism. *a*, Virion parental DNA (solid lines) showing inverted terminal repetition (sequence a b c); *b*, hairpin formation at the 3' end of either strand (sequence a complementary to sequence d); *c*, daughter strand synthesis in the 5' to 3' direction using the 3'-OH from the parental strand as primer, and site-specific endonuclease introducing a ss nick near sequence d; *d*, strand displacement within hairpin and completion of terminal 3' ends; *e*, products of a second round of replication by the same mechanism. Model proposed by Roberts⁸ and Wu *et al.*⁹. The events shown could occur at the end of a round of replication (to complete the 5' ends of progeny strands) rather than at initiation as shown.

to form circles after digestion of the 3' ends with exonuclease III. We find this is not the case. Viral DNA was extracted from HEK cells infected with human adenovirus type 5 (Ad5). After digestion of 0.1%, 0.75%, 1.3% and 1.6% of the double-stranded molecules in one experiment and 0.1%, 0.7%, 1.1% and 1.5% in a second experiment, the intracellular viral DNA was annealed. Circular molecules that sedimented faster than linear Ad5 DNA were not observed (Fig. 2). Samples from one experiment were also examined in the electron microscope and no circular molecules were observed. In a control experiment with T7 DNA¹⁵, using similar digestion and annealing conditions, circle formation was observed in DNA digested to 0.9% of the molecule (Fig. 2) and 89% of molecules were circular by electron microscopy, whereas T7 DNA failed to circularise when digested to only 0.15%. These results indicate that non-inverted terminal repetitions of the type shown in Fig. 1d do not occur within the terminal 260 bases of replicating Ad5 DNA, as has been reported previously for mature DNA isolated from virions^{15,16}. As the terminal sequence is not palindromic (J. R. Arrand and R. J. Roberts, in preparation), we conclude that inversion of the termini during replication, which is a logical consequence of the hairpin-primed model for non-palindromic termini (Fig. 1), does not occur during adenovirus DNA replication. It is interesting to note that there is evidence for a terminal palindromic base sequence in AAV DNA⁶, supporting other evidence for a hairpin-primed mechanism for AAV DNA replication.

The hairpin-priming model also requires covalent addition of progeny DNA to a hairpin on the parental strand (Fig. 1). Some or all of the pulse-labelled viral DNA should therefore sediment faster than virion DNA in alkali and should contain sequences that spontaneously renature on rapid transfer to conditions in which duplex DNA is stable. But, fast sedimenting pulse-labelled adenovirus DNA has not been observed in alkaline gradients^{2,10,17}, and we have been unable to detect spontaneously renaturing sequences in replicating adenovirus DNA by chromatography on hydroxylapatite (data not shown). This may be because the replication intermediates predicted by the model are highly transient, but such intermediates were observed during AAV DNA replication^{8,18}.

We tested a further prediction of the hairpin-primed model for adenovirus DNA replication which is independent of the exact nature of the terminal sequences and whether self-priming occurs at initiation or termination of synthesis. It can be seen from Fig. 1 that the model predicts a strand switch in which the original 3' terminus becomes the 5' end of progeny strand, to be replaced by newly replicated DNA at the 3' end of the parental strand. Thus all newly replicated molecules should have newly replicated DNA at both 3' ends of the double-stranded DNA. This was tested experimentally by pre-labelling Ad5 DNA with ³H-thymidine and then transferring to medium containing ³²P and 5-bromodeoxyuridine (BUdR) (Fig. 1). If the model is correct, molecules that had undergone one round of replication in BUdR, isolated as a peak of hybrid (LH) density in CsCl, should have all their 3' ends labelled with ³²P. But, 50% of the 3' ends of LH DNA should be labelled with ³H rather than ³²P if there is no terminal strand switch during replication. The nature of the label at the 3' ends of LH DNA isolated from infected cells by CsCl equilibrium density centrifugation and hydroxylapatite chromatography was examined by exonuclease III digestion. Figure 3 shows the release of ³H-thymidine acid-soluble counts plotted as a function of the release of ³²P acid-soluble counts by exonuclease III digestion. The points form a straight line through zero, without the delay in release of ³H predicted by the model. The 95% confidence limits for the intercept of the curve indicate that a strand switch of less than 16

bases cannot be excluded, but such a short switch is not consistent with terminal sequence data (J. R. Arrand and R. J. Roberts, in preparation). Figure 3 also shows the expected curve if a strand switch of 120 base pairs occurred (that is, the smallest possible hairpin from sequence data). In this case, the intercept would be 0.68% ³²P counts released and zero ³H counts released, but this is clearly not the observed result. The discrepancy between our result and that predicted by the model is unlikely to be an experimental artefact. Contamination of LH DNA with ³H-LL DNA was not detectable by recentrifugation. Recombination between replicating molecules was not detectable as ³²P radioactivity entering the LL (³H) peak. Continued incorporation of ³H after the shift to ³²P, BUdR medium was prevented by adding a 33-fold excess of BUdR over the original ³H-thymidine concentration and addition of 5-fluorodeoxyuridine. Nearly all molecules labelled in a 3-h period would be mature, without gaps at which exonuclease could act, and completed molecules were further selected by using only the centre of the peak of LH molecules, and centrifuging the sample a second time in CsCl.

We have presented evidence that hairpin priming does not

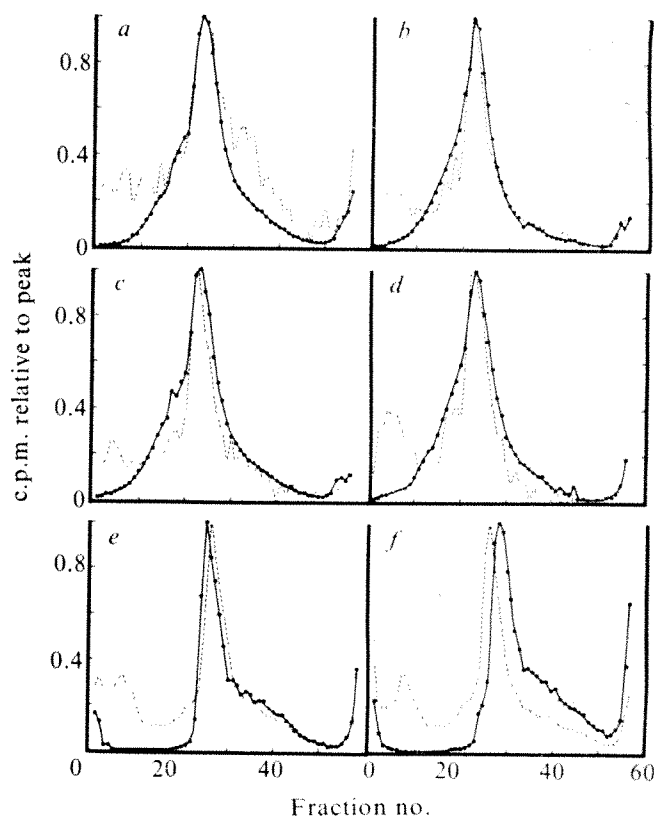

Fig. 2 Neutral sucrose gradient sedimentation of pulse-labelled Ad5 DNA and T7 DNA after exonuclease III digestion and annealing. Human (HEK) cells were infected with 5 plaque-forming units per cell Ad5 and labelled with ³H-thymidine from 16 to 17 h after infection. Viral DNA, isolated by a modification of the Hirt procedure²², neutral sucrose gradient centrifugation and hydroxylapatite chromatography, was digested for various times with *E. coli* exonuclease III, annealed for 30 min at 65 °C and slowly cooled to room temperature and centrifuged through a 5–20% neutral sucrose gradient (SW27, 18 h, 16,000 r.p.m. at 4 °C). ³²P labelled Ad5 DNA was added as marker (○); ³H-thymidine (●). Assuming Ad5 DNA contains approximately 35,000 base pairs, the extent of digestion from each 3' end would be 0.1% = 15 bases (a); 0.7% = 120 bases (b); 1.1% = 190 bases (c) and 1.5% = 260 bases (d). Lower panels: T7 DNA control digested to 0.15% (e) and 0.9% (f), annealed and centrifuged in similar conditions (●), with ³²P CELO virus DNA as marker (MW 29 × 10⁶)¹⁵. Sedimentation was left to right.

Fig. 3 Release of ^3H and ^{32}P acid soluble counts from LH DNA by exonuclease III digestion. Ad5 infected HEK cells were pre-labelled with ^3H -thymidine ($20 \mu\text{Ci ml}^{-1}$, $5 \times 10^{-7} \text{ M}$) from 6 to 16 h after infection and then washed and labelled with ^{32}P and $5 \mu\text{g ml}^{-1}$ BUdR, ($1.6 \times 10^{-5} \text{ M}$) in the presence of $0.5 \mu\text{g ml}^{-1}$ 5-fluorodeoxyuridine from 16 to 19 h after infection. Viral DNA was isolated by a modification of the Hirt procedure²², ribonuclease treated and centrifuged to equilibrium in a CsCl gradient (initial density 1.730 g ml^{-1}) in a Ti50 rotor at 33,000 r.p.m. for 64 h at 20°C . The centre of the LH DNA peak was collected and recentrifuged in a similar equilibrium gradient, purified by hydroxylapatite chromatography and digested with *E. coli* exonuclease III. ●, % Release of ^3H counts plotted against percentage release of ^{32}P counts; dashed line, expected curve if the strand switch in Fig. 1 involves 120 base pairs (see text).

occur in adenovirus DNA replication. Wu *et al.*⁹ observed some type of secondary structure at the ends of adenovirus type 2 DNA in the electron microscope, but they could not conclude whether their data supported the hairpin structure shown in Fig. 1. There is no other published evidence for hairpin priming in adenovirus DNA replication, although there is considerable evidence for such a mechanism of replication at the 5' ends of other linear viral DNA chromosomes^{5-7, 18-21}. Although the absence of hairpin-priming in adenovirus DNA replication does not indicate the mechanism by which the 5' ends of progeny DNA are replicated, we have proposed an alternative model for adenovirus DNA replication in which the terminal 55,000 MW protein binds deoxycytidine and recognises the inverted terminal repetition, providing the free 3'-OH to prime DNA synthesis¹¹. This model is consistent with data presented above and all known data concerning adenovirus DNA replication, and suggests a function for both the 55,000 MW protein and terminal repetition. It will be interesting to determine whether replication of the ends of eukaryote chromosomes is primed by hairpin loops as originally proposed by Cavalier-Smith³, by a protein-bound nucleotide as we have proposed for adenovirus¹¹, or by some other mechanism as yet unknown.

We thank Dr H. B. Younghusband for helpful discussions and electron microscopy, Dr I. R. Lehman for *E. coli* exonuclease III and Miss A. Tandy for technical assistance.

Benzo[a]pyrene diol epoxide covalently binds to deoxyguanosine and deoxyadenosine in DNA

CHEMICAL carcinogens, for example, benzo[a]pyrene (BaP), are metabolised to reactive intermediates which bind covalently to cellular macromolecules¹⁻³ and the extent of binding seems to correlate with the carcinogenic potency of the hydrocarbons¹. Through various mutagenicity, metabolism and binding studies, the intermediate which undergoes formation of a stable covalent complex with DNA has been identified as 7 β ,8 α -dihydroxy-9 α ,10 α -epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene (BaP diol epoxide)⁴⁻⁹. The structure of a covalent adduct formed between this hydrocarbon and poly(G) has also been established⁸⁻⁹. We report here the identity of several adducts obtained by reacting (\pm)BaP diol epoxide with tritium-labelled DNA. Four differently labelled lots of DNA were synthesised *in vitro* with DNA polymerase I by incorporating in each case three unlabelled and one tritium labelled nucleoside triphosphate. Through the use of this unambiguous labelling technique we have demonstrated that activated BaP forms two adducts with deoxyguanosine, two with deoxyadenosine and possibly one with deoxycytidine, while reaction with deoxythymidine was not detected. This approach also allowed the relative percentage of each adduct to be calculated. The deoxyguanosine adducts predominated and constituted 92% of the total stable covalent adducts formed.

(\pm)BaP diol epoxide was synthesised as previously described^{10,11}. Covalent binding of adducts to calf thymus DNA was carried out at neutral pH by enzymatic activation of ^3H -BaP or reaction of unlabelled or ^{14}C -(\pm)BaP diol epoxide directly with the nucleic acid. The phosphodiester backbone of the DNA was enzymatically hydrolysed and the products were chromatographed on Sephadex LH-20. Hydrophobic material eluting from the column was concentrated and further analysed by high pressure liquid chromatography (HPLC).

Figure 1a shows a HPLC profile of hydrolysis products resulting from a co-injection of unlabelled DNA reacted with (1) ^3H -BaP plus microsomes and (2) unlabelled (\pm)BaP diol epoxide. Chromatography of DNA-BaP diol epoxide adducts alone results in a fluorescence trace identical with that of Fig. 1a. But, chromatography of the microsome catalysed adducts alone results in detection of

peaks 1, 4, 5 and 7 only. Therefore, the reaction between (\pm)BaP diol epoxide and DNA yields three more adducts (peaks 2, 3 and 6) than BaP plus microsomes and DNA.

The bases to which (\pm)BaP diol epoxide binds were identified by reacting ^{14}C -(\pm)BaP diol epoxide with each of four samples of ^3H -labelled DNA. The DNA samples were labelled unambiguously with ^3H in either deoxyguanosine,

Fig. 1 HPLC profiles of BaP and (\pm)BaP diol epoxide-DNA adducts were carried out on a Varian model 8500 fitted with two columns (Waters μ Bondapak C_{18} , 4 mm \times 30 cm) in series and eluted with 50% methanol water. BaP covalent adducts were isolated after reaction of [^3H]BaP with DNA in the presence of NADPH and rat liver microsomes from animals pre-treated with 3-methylcholanthrene. Alternatively, unlabelled or ^{14}C -(\pm)BaP diol epoxide was reacted directly with unlabelled or ^3H -labelled DNA in the same conditions as the enzyme activation of the hydrocarbon. The unlabelled or ^{14}C -(\pm)BaP diol epoxide was used at the same concentration as the ^3H -BaP. The ^3H -labelled DNA's were enzymatically made by incorporation of three unlabelled and one ^3H -labelled nucleoside triphosphate with DNA polymerase from *Escherichia coli*. Calf thymus DNA, untreated, was used as template. The labelled nucleoside triphosphate was used undiluted and this procedure resulted in DNA with a specific activity of $14 \mu\text{Ci mg}^{-1}$. Four DNA samples were synthesised with ^3H located in either (1) deoxyguanosine, (2) deoxyadenosine, (3) deoxycytidine or (4) deoxythymidine. After reaction of the hydrocarbon with DNA any protein was removed by phenol extraction. The DNA was precipitated with ethanol and the precipitate heated to remove intercalated hydrocarbon. The DNA was enzymatically hydrolysed and hydrophobic material isolated by Sephadex LH-20 chromatography. The HPLC profiles represent adducts obtained from LH-20 columns. *a*, Co-injections of ^3H -BaP plus microsomes reacted with unlabelled DNA and unlabelled (\pm)BaP diol epoxide reacted with unlabelled DNA and *b*, ^{14}C -(\pm)BaP diol epoxide reacted with ^3H -deoxyguanosine-labelled DNA.

Fig. 2 HPLC profile of LH-20 samples isolated as described in Fig. 1 after reaction of ^{14}C -(\pm)BaP diol epoxide with *a*, ^3H -deoxyadenosine labelled DNA and *b*, ^3H -deoxycytidine labelled DNA.

deoxyadenosine, deoxycytidine or deoxythymidine. The four samples of labelled DNA were prepared by incorporating three unlabelled triphosphates and one ^3H -labelled triphosphate into calf thymus DNA by *Escherichia coli* DNA polymerase I. The reaction conditions were essentially as previously described¹², except that the DNA template was untreated and the tritiated nucleoside triphosphate was not diluted with cold material. The labelled DNA was ethanol-precipitated, dialysed, reacted with ^{14}C -(\pm)BaP diol epoxide and the covalent adducts were isolated after hydrolysis and Sephadex LH-20 chromatography. The results of three of the four double label experiments are presented in Figs 1*b*, 2*a* and 2*b*. HPLC of these samples resolved five ^{14}C -labelled adducts. Figure 1*b* represents reaction of ^{14}C -(\pm)BaP diol epoxide with ^3H -deoxyguanosine labelled DNA. Peaks 3 and 5 contain both ^3H and ^{14}C and therefore represent hydrocarbon-deoxyguanosine adducts. From the specific activities of both the hydrocarbon and base a 1:1 ratio of the two components was calculated. Similar inspection of Fig. 2*a* and *b* identifies peaks 6 and 7 as deoxyadenosine adducts while peak 4 may be a deoxycytidine complex. Assignment of this adduct must remain tentative because of the lack of complete symmetry and coincidence of the ^3H and ^{14}C . Reaction of deoxythymidine was not observed despite our ability to detect approximately 1 adduct per 2.5×10^7 base pairs. The relative percentage of each adduct formed is shown in Table 1. Binding occurred to the extent of 92% deoxyguanosine, 5% deoxyadenosine, 3% deoxycytidine

and 0% deoxythymidine. These results are not in accord with those obtained by reaction of (\pm)BaP diol epoxide with model nucleic acids¹³, where the hydrocarbon reacted with poly(G), poly(A) and poly(C) to a similar extent. The reactions with model systems were carried out in 50% acetone which would have denatured the nucleic acids¹³, while the conditions used here were more favourable to maintaining helical conformation. The differences in reaction conditions may explain the relative lack of binding asymmetry found with the model systems.

Two adducts were obtained for both deoxyguanosine and deoxyadenosine and this could also be the case for deoxycytidine since peak 2 was not identified and could represent a second deoxycytidine adduct. The formation of two adducts with each base could have resulted either from the reaction with both stereoisomers of (\pm)BaP diol epoxide or alternatively a single isomer forming *cis* and *trans* addition products. Reaction of (\pm)BaP diol epoxide with poly(G) results in predominately *trans* addition of equal amounts of both stereoisomeric hydrocarbons⁶. We also analysed the adducts formed between (\pm)BaP diol epoxide and poly(G) by HPLC and circular dichroism spectroscopy. In confirmation of the results of Weinstein *et al.*⁶, we found that two major adducts were formed in about equal amounts and correspond to reaction of (+) and (−)BaP diol epoxide. In addition, two minor adducts were found which could represent (+) and (−)BaP diol epoxide reacting by *cis* addition of the guanine base.

Only one deoxyguanosine adduct was formed with the microsome system. This probably represents *trans* addition of only one enantiomer since enzymatic formation of BaP diol epoxide is stereoselective¹⁴. Two adducts were formed by reaction of (\pm)BaP diol epoxide with DNA and by analogy with the poly(G) system correspond to adduct formation with the (+) and (−) enantiomers of the hydrocarbon. In contrast to the poly(G) system where diastereomers are formed in approximately equal amounts, the DNA adducts occur at 90% and 10% for deoxyguanosine and 80% and 20% for deoxyadenosine. The amounts of the two adducts with deoxyguanosine and deoxyadenosine tend to equalise on binding of the hydrocarbon to heat denatured DNA. Also, there is an increase in the overall proportion of deoxyadenosine adducts. These results suggest that the asymmetric binding of the two stereoisomers of (\pm)BaP diol epoxide is less with single-stranded DNA than with double-stranded DNA. The preferential reaction of one enantiomer with DNA may be related to the dissymmetry of the right-handed helix, while the increase in deoxyadenosine adducts may result from topological changes in DNA conformation. Thus, the rates, sites and amounts of products obtained by reacting activated BaP with nucleic acids are probably controlled to a large degree by the amount of helical form and the conformation of the polymer. Of the adducts which have not been characterised the identity of peak 2 remains unknown while peak 1 co-chromatographs by HPLC with a hydrolysis product of (\pm)BaP diol epoxide. The high-resolution mass spectrum of the main deoxyguanosine adduct (peak 5) is

consistent with a structure in which the 10-position of the hydrocarbon is attached to the *N*²-exocyclic amine of the base. This structure is analogous to that obtained by reacting (\pm)BaP diol epoxide with poly(G)⁶. Quantitatively the most important adduct is binding to the exocyclic amine of guanine. Since (\pm)BaP diol epoxide formed adducts only with those bases containing a free amino group it is possible that this is the preferred binding site of the hydrocarbon.

In addition to the results reported here two other studies have indicated that BaP activation occurs by formation of the diol epoxide^{4,6}. But, evidence for other, as yet uncharacterised, intermediates has been presented^{15,16}. The difference in these results and ours may lie in the reaction conditions used. We find that magnesium chloride at 1 and 5 mM inhibits microsomal mediated binding of BaP to DNA by 60% and 75%, respectively. Since magnesium chloride was used in these studies^{15,16} it might account for the sixfold lower binding which was obtained compared with our results. If magnesium chloride specifically affected BaP diol epoxide binding another type of adduct could accumulate which would otherwise be a minor component. Even if other binding adducts do occur the importance of studying BaP diol epoxide rests on the observation that it is the most biologically active metabolite of BaP yet described^{8,21,22}.

In addition to the base adducts reported here, (\pm)BaP diol epoxide catalyses DNA and RNA strand scission¹⁷. Despite the fact that 250–300 base adducts are formed for each strand scission¹⁷ the relative importance, and indeed physiological significance, of each of these processes are unknown. Ethyl nitrosourea forms alkyl phosphotriesters and strand scissions which are lethal¹⁸. Since (\pm)BaP diol epoxide undergoes similar reactions this could account for some of the cytotoxic properties of BaP¹⁹. Furthermore, the excision repair of adenine carcinogen adducts in a number of cases is known to occur at a greater rate than those of guanine²⁰. The *N*²-exocyclic amine adduct of deoxyguanosine-BaP diol epoxide may therefore have a relatively long biological half life. As cancer induction occurs over a long period of time this may be an important adduct in the biological transformation caused by BaP.

We thank A. L. Burlingame for the high resolution mass spectrum and NCI for the ¹⁴C-(\pm)BaP diol epoxide. This work was supported in part by the US ERDA Division of Biological and Environmental Research and NCI, contract Y01-CP50203.

matters arising

General relativistic incompressibility

COOPERSTOCK and Sarracino¹ have attempted to redefine the concept of incompressibility in general relativity. Their result, if correct, would lead to a higher allowable maximum redshift from the surface of a bound object than is usually said to be permitted². We point out here a serious physical difficulty associated with their work. In calculating the mass of an equilibrium configuration in general relativity, the local mass density (a scalar quantity) can always be related to the pressure through an equation of state established in an inertial reference frame, without regard to the local gravitational potential. Nonetheless, Cooperstock and Sarracino choose to define a constant proper mass density $\rho_{\text{proper}} \equiv \rho(r)/g_{rr}^{1/2} = \text{constant} = a$ (say). They then compute a stellar mass from the relation

$$M = \int_0^r \rho_{\text{proper}} 4\pi r^2 g_{rr}^{1/2} dr \quad (1)$$

where g_{rr} is the radial component of the metric tensor. This definition of the mass is correct, being simply the general relativistic expression with $\rho_{\text{proper}} g_{rr}^{1/2}$ in place of $\rho(r)$.

As $\rho(r)$ is already a scalar, however, ρ_{proper} has no well defined physical significance. The division of the integral for mass into a product of a 'proper' volume and 'proper' density is arbitrary and misleading. Cooperstock and Sarracino, in asserting that the global contribution of gravitation to the overall mass-energy of a star will affect the local stress tensor, have missed the point of the equivalence principle, the very foundation of general relativity. The validity of this proposition guarantees that ρ itself (not $\rho/g_{rr}^{1/2}$) is what one would measure when applying an 'ergometer' to a small piece of matter, whether it was inside a neutron star or in empty space. In principle, the source stress tensor $T_{\mu\nu}$ appearing on the right hand side of the field equations $G_{\mu\nu} = kT_{\mu\nu}$ should contain all sources of mass-energy except gravitation. In practice, the gravitational binding energy of two neutrons, whether 10^{28} or 10^{-13} cm apart is negligible. Therefore ρ is the physical quantity relevant for local dynamical effects in neutron stars.

Nonetheless, following the procedure of Tolman³, one can treat the relation $\rho(r) = ag_{rr}^{1/2}$ as a defining equation for the radial variation of $\rho(r)$ and then deduce the equa-

tion of state $p = p(\rho)$. In that case, the equation of hydrostatic equilibrium is still given by⁴

$$\frac{dp}{dr} = -\frac{GM(r)\rho(r)}{r^2} \left[1 + \frac{p(r)}{\rho(r)c^2} \right] \times \left[1 + \frac{4\pi r^3 p(r)}{M(r)c^2} \right] \left[1 - 2GM(r)/rc^2 \right]^{-1} \quad (2)$$

Substituting $ag_{rr}^{1/2}$ for $\rho(r)$ and noting that in a physically allowable object p must be positive, all the terms on the right hand side of equation (2) must be positive, so that the pressure decreases with radius, that is $dp/dr < 0$. Now the numerical results of Cooperstock and Sarracino¹ show that $p(r)$ decreases with increasing $g_{rr}^{1/2}$, that is

$$dp/d(g_{rr}^{1/2}) < 0$$

But since $\rho(r) = ag_{rr}^{1/2}$ must be a positive quantity, $dp/d\rho < 0$. This is an unstable and unphysical situation. In order to have microscopic stability⁴, one requires $dp/d\rho > 0$. Furthermore, dividing dp/dr by $dp/d\rho$, one finds $dp/dr > 0$. It is hard to imagine that a physically realistic star with ρ increasing outward can be made. Though the resulting configuration is in equilibrium since it is a solution to the general relativistic hydrostatic equilibrium equation, it is unstable. Therefore, the resulting star constructed from Cooperstock and Sarracino's definition of incompressibility in general relativity is physically unrealisable. It seems that the redshift limit $z = 2$ set by Bondi² remains the largest allowable surface redshift consistent with both general relativity and microscopic stability.

COOPERSTOCK AND SARRACINO REPLY—For Brecher and Wasserman, ρ_{proper} would have "well defined physical significance" only if it were completely invariant. In earlier correspondence, we had directed them to the equivalence principle, noting that this

principle renders such invariance *a priori* unattainable. The equivalence principle implies that the gravitational field can be locally transformed away by free-fall. That is not the point. The point is that with respect to a frame at rest relative to a spherically-symmetric body, ρ_{proper} certainly is well defined. It assumes the form $\rho g_{rr}^{-1/2}$ in Schwarzschild coordinates. This form has been justified by Misner and Sharp^{1,2} from dynamical considerations. We have justified the form from static considerations, and the extension has been made to charged fluid spheres (F.I.C. and R.S.S., in preparation, also, F.I.C. and V. de la Cruz, in preparation). In another coordinate system, say isotropic coordinates, it would not assume this form, but rather be determined by the integrand of the energy integral of the body over proper volume

$$M(r) = \int_0^r \rho_{\text{proper}} dV_{\text{proper}}$$

All energy, including gravitational energy, contributes to the total mass of the body and hence ρ_{proper} , which includes all energy, is the physically relevant quantity in general relativity. The failure to recognise its central role has been perpetuated by Newtonian conditioning.

On the one hand, Brecher and Wasserman assert that the validity of the equivalence principle guarantees that ρ and not ρ_{proper} is what their "ergometer" will measure. On the other hand, they then say that the gravitational binding energy of two neutrons, even 10^{-13} cm apart, is very small at any rate. If the energy is not there in principle, why worry about it in practice?

We feel that Brecher and Wasserman miss the point again. Certainly the gravitational binding for two neutrons is negligible. But, we are not concerned here about two neutrons nor indeed, necessarily about neutrons. We are concerned about conditions where large amounts of matter are being compressed towards their limit and gravitational energy is very significant indeed. This significance is made quite evident in the distinction between the bodies which satisfy the $\rho = \text{constant}$ and $\rho_{\text{proper}} = \text{constant}$ equations of state. We are not "asserting that the global contribution of gravitation to the overall mass-energy of a star will affect the local stress tensor ($T_{\mu\nu}$) . . .". We are asserting that the local contribution of gravitational energy, in addition to $T_{\mu\nu}$, determines the physically relevant proper total energy density.

Without entering the controversy regard-

Fig. 1 Calculated differential melting curve for the block-random DNA sequence containing 4,002 base pairs. It consists of three blocks 1,334 base pairs long with GC contents of 0.43, 0.50 and 0.57. The sequences within each of these blocks were obtained using a random digits generator. The calculations were performed by the method of Poland⁵ for a standard set of the DNA thermodynamic parameters (see for example ref. 7). $\sigma = 5 \times 10^{-5}$; $T_{AT} = 340$ K; $T_{GT} = 380$ K; $U_{AT} = 8$ kcal mol⁻¹; loop-weighting exponent $\alpha = 1.5$. The negative value of the derivative of the degree of helicity θ with respect to temperature is plotted as ordinate and the difference between the temperature and the value $T_0 = 360$ K being an abscissa.

ing superluminal sound, we can certainly state that $d\rho/d\rho_{\text{proper}}$ is non-negative. One does not have to pursue the analysis of Brecher and Wasserman to determine that $d\rho/dr > 0$ for the $\rho_{\text{proper}} = \text{constant}$ equation of state. This is obvious from Buchdahl's proof. The point is that ρ_{proper} does not increase with r . To paraphrase Brecher and Wasserman, we would find it hard to imagine that a physically realistic star with ρ_{proper} increasing outward can be made. Clearly our equation of state was chosen as the limiting case which fulfills this requirement.

The nature of the fine structure of DNA melting curves

SEVERAL reports¹⁻⁶ have suggested that the differential melting curves of DNA from various bacteriophages (including λ , T7, S_D, PM2 and fd) have a clear-cut fine structure. This fine structure is seen as a series of sharp peaks

with half-width of about 0.3° . Experimental results obtained in the various laboratories correlate well and thus one can suggest that fine structure of the differential melting curves is a general feature of all DNA's containing several tens of thousands or less of base pairs. It is clear also that a particular profile of the differential melting curve reflects a particular sequence of base pairs. Wada *et al.*⁶ have gone further and concluded that the fine structure is evidence of the existence in DNA of homostability regions characterised by highly homogeneous sequences largely different from random ones. They came to this conclusion because of their failure to obtain theoretically differential melting curves resembling experimental curves for the case of a random sequence of base pairs (see refs 2 and 4).

In contrast to the findings of Wada *et al.* we have shown⁷ that the existing helix-coil transition theory predicts the effect of fine structure in the differential melting curves for purely random sequences. The theory explains all main features of the observed effect including the width of the individual peaks, the dependence of the effect on number of base-pairs in the genome, on the state (closed or open) of circular DNA and so on (for details see ref. 5).

It has long been known that in many instances DNA consists of blocks

which differ from one another in their GC content, but inside such blocks the distribution of base pairs has been thought to be quasirandom (see for example ref. 7). λ DNA presents a classic example of such block sequences. It is clear that DNA with a block sequence will melt within broader temperature interval and simply because of this it will exhibit much greater fine structure than DNA of the same length but of random sequence (that is, consisting of a single block). In fact, in random DNA the different peaks overlap each other and smooth off the fine structure. Experimentally this tendency is shown dramatically when quasirandom T7 DNA is compared with the block λ DNA which is virtually as long but has a differential melting curve with very much more distinct fine structure.

An even more impressive example of a differential melting curve with very distinct peaks was presented by Wada *et al.*⁶. They measured the differential melting curve for the replicative form of fd DNA. This DNA consists of only about 6,000 base pairs but its differential melting curve contains as many as seven well resolved peaks.

To simulate something similar to this we have generated a sequence containing 4,002 base pairs divided in three blocks each consisting of 1,334 base pairs with the GC contents of 0.57; 0.50 and 0.43. These values were chosen so that the resultant melting curve for our artificial sequence should be as wide as the experimental curve for fd DNA. Within each block a sequence was obtained with the aid of a generator of random digits. The theoretical differential melting profile for such sequence is shown in Fig. 1. This profile consists of at least six well resolved peaks and bears a strikingly close resemblance to the experimental profile presented by Wada *et al.*⁶.

Thus we conclude that the fine structure of differential melting curves can be explained quite plausibly by the theory of helix-coil transition under the assumption that only quasirandom or block-quasirandom sequences exist. So the observed sharp peaks on the differential melting curves can not be considered as evidence for existing homostability regions, that is, sufficiently long sequences consisting of repeating short segments which contain a fixed number of AT and GC pairs as Wada *et al.*⁶ have claimed.

Crustal and *in situ* origin of Norwegian eclogites

KROGH¹ in a study of Norwegian eclogites concludes that all these eclogites can represent crustal rocks metamorphosed *in situ* during subduction to depths of 60–85 km. To show that eclogites are metamorphosed *in situ* demands that their conditions of formation are replicated in the adjacent amphibolite, or occasionally granulite facies, gneisses¹. In the western parts of Krogh's area eclogite equilibration conditions are $T \sim 800^\circ\text{C}$, $P \sim 23$ kbar¹. There are, however, no gneiss parageneses compatible with such conditions in which plagioclase is unstable². Thus applying geobarometric techniques^{3,4} to a pegmatite, said to be genetically related to adjacent eclogite⁵, maximum pressures are 12 kbar (ref. 3) or 13.2 kbar (ref. 4) for an assessed $T = 700^\circ\text{C}$. The occurrence of margarite in meta-anorthosites associated with eclogite⁶ gives maximum pressures of about 9 kbar⁷.

For Norwegian eclogites to be crustal demands that either their bulk chemical variations are controlled only by low- P fractionation, or that transitions from parent basalts and so on can be seen. I know of no unequivocal examples of the latter.

Krogh¹ does not seem to distinguish between the country-rock eclogites⁸ he describes and eclogites within ultramafic masses^{9,10}. He ignores critical evidence from the latter association that clinopyroxene, orthopyroxene and garnet show exsolution relationships^{9,10} which suggest high T - P conditions (1,100–1,600 $^\circ\text{C}$, 20–40 kbar) not compatible with crustal metamorphism or a subduction regime. He also ignores the description of orthopyroxene exsolving garnet from a country-rock eclogite¹¹ (recent work¹² suggests $T = 1,200$ – $1,370^\circ\text{C}$, $P = 30$ – 33 kbar).

Krogh demonstrates that there are regional variations in conditions of eclogite equilibration and that these conditions vary with time. He does not show how the eclogites reached this equilibrium. Exsolution data suggest that some eclogites at least,

formed from high- P liquids^{10,11} and are neither crustal nor *in situ*.

Paradoxically continent–continent collision processes¹ also seem a likely scenario for such rocks though dominated by deep level obduction¹² rather than subduction processes¹.

KROGH REPLIES—From the first sentences and the conclusion of my article¹, it should be quite clear that I am dealing with eclogites within gneisses. Low- P (<10 kbar) fractionation may, in fact, be responsible for chemical variations within eclogites². Several lines of evidence also suggest that some of the eclogites may represent meta-sediments³. Transitions from parental low- P igneous to eclogitic parageneses are in fact, described from several localities (refs 4–7 and Bryhni & Wickström personal communication).

Gneisses from Hareidland contain plagioclase–clinopyroxene symplectites along with garnet + Ksp ± bto + rutile^{2,8}, thus indicating an originally eclogitic paragenesis in which plagioclase was unstable.

Analyses of co-existing garnet + clinopyroxene pairs from granulites at Måløy show that the $K_D^{\text{garnet-clinopyroxene}}$ values here are equal to those in adjacent eclogites (L. Malinconico, personal communication). This indicates similar metamorphic conditions in these two rock types.

Margarite in meta-anorthosite associated with eclogites is suggested by Lappin⁹ to be related to local amphibolitisation of the eclogites.

The pegmatite referred to¹¹ may well be from the field and petrographic descriptions⁸ post-eclogitic. Lappin's¹¹ limitations on the maximum pressure attained by the gneisses are thus related to later, post-eclogite events.

I have demonstrated the variation in metamorphic conditions with time by studying the chemical zoning of the minerals of the eclogites.

The inferred increase in P and T from, for example, 9.6 kbar, 505 $^\circ\text{C}$ to 17.6 kbar, 720 $^\circ\text{C}$ (ref. 1, Table 1) must be regarded as a rather marked variation. I further reported relict blueschist facies mineralogy in eclogites from Sunnfjord. In these samples, the cores of both garnet and amphibole have compositions typical for blueschist facies¹⁰, while the rim compositions are more typical for eclogites within gneisses^{10,12}. Furthermore, inclusions of low- P metamorphic mineral assemblages are fairly common in the garnets of eclogites from Nordfjord^{1,5,13} and Sunnfjord¹, indicating that prograde metamorphism has produced the eclogite mineralogy.

These variations all indicate that a large increase in P and T occurred with time at individual localities, as well as from east to west across the Gneiss Region.

With regard to the exsolution phenomena in pyroxenes^{14–16}, the exsolution history is still ambiguous. The existing chemical data are not satisfactory since the chemical zoning in the exsolved phases is not investigated. These data^{14–16}, however, still tend to give equilibrium conditions that fall within the regional P - T pattern defined for the whole area¹. A more extensive discussion of the crustal and mantle derivation of Norwegian eclogites will soon be available⁵.

The evidence of mineral zoning in individual samples, and the regional variation in equilibrium conditions strongly argues that the eclogites I have studied were formed by *in situ* prograde metamorphism of crustal rocks. This does not exclude the possibility that some of the components of this terrane, such as the ultrabasic masses, may have been introduced from the mantle^{5,11,16}.

reviews

Wonderful contrivances

N. Feather

Perpetual Motion: The History of an Obsession. By Arthur W. J. G. Ord-Hume. Pp. 235. (Allen and Unwin: London, 1977.) £50.

THE subtitle of this book *The History of an Obsession* is significant in its place: the study is one of unrelieved failure (and a modicum of fraud); of inevitable failure when the products of obsessive fantasy are examined for sober fact. It is also apposite in another connection. In his Acknowledgements and Preface, and casually in asides throughout the text, the author gives a brief history of his own thralldom to his subject.

Mr Ord-Hume is a qualified mechanical engineer, with a successful career as a small-aircraft designer behind him, whose first encounter with the perpetual-motion saga was at his father's knee: "[My Father] used to tell me about it all when I was very small." Then, at university, his persistent importuning of one professor in particular at last brought the injunction never "to mention the subject again". In later life Mr Ord-Hume began a file of literature references to perpetual motion, as a by-product of research for other writings. The file grew and grew. Finally, a few years ago, the BBC's producer of *Horizon* planned a programme on perpetual motion, and he was asked to help. As he reports: "For several weeks I became thoroughly steeped in this subject, exploring in depth the references which I had filed away over the years . . . [the] material ended up in the form which you now have in your hands".

The form, alas, is not entirely prepossessing, there are footnotes with references to cited literature, there are four pages of bibliography and an index of more than six pages, indeed the trappings of a scholarly work, but the writing is far from scholarly. (On the author's behalf it should, however, be said that it was not his intention to write academically—rather to provide "a subjective history of the quest for the impossible".) Mr Ord-Hume should at least, however, have supervised his indexer. A single person referred to in different places in the text under slightly different guises (as Edward J.

Wood, rather than as Wood *simplificiter*, or as Edward Somerset, rather than as the Marquis of Worcester) is apt to be indexed under each guise, without cross-reference—and the author himself might well have considered the item "Ord-Hume, author, quoted" as supererogatory!

More serious, for whatever readership he was consciously writing, Mr Ord-Hume should have made sure that he got his elementary physics right. His version of Newton's first and third laws will pass muster, but his second law will not—"When a force acts upon a body in motion, the effect of this action is the same, in magnitude and direction, as if it acted on the body at rest." His version of the second law of thermodynamics reads: "heat cannot be increased without the expenditure of more work: it cannot run uphill".

There is much, then, to irritate the knowledgeable, or confuse the tyro, in this book, but there is also a wealth of solid information, and a gallery of illustrations (some ninety of them)

of the strange and wonderful contrivances from none of which, in the upshot useful work was obtained without drawing on an external source of energy (some, in fact, were never intended to do external work—the self-winding clocks, for example). The illustrations alone provide interest and instruction; it is convenient to have them in a slender (and not immoderately priced) volume. Apart from this aspect, however, the serious engineer will probably in the end find it necessary to seek out the two-volume work of Dircks (vol. 1, 1861; vol. 2, 1870) in the library, if he wishes to pursue the subject in depth.

Mr Ord-Hume may claim to have brought the story up-to-date by the inclusion of Strutt's radium clock, the Wilberforce pendulum and the breeder reactor as objects of discussion—but again, I fear, he has garbled the physics in the process. □

N. Feather is Emeritus Professor of Natural Philosophy at the University of Edinburgh, UK.

Plant cell and tissue culture

Applied and Fundamental Aspects of Plant Cell, Tissue and Organ Culture. Edited by J. Reinhart and Y. P. S. Bajaj. Pp. 803. (Springer: Berlin, Heidelberg and New York, 1977.) DM190; \$83.60.

PLANT CELL and tissue culture is developing into an active and exciting area of research and is permitting novel lines of investigation in the various plant sciences. *In vitro* techniques are being widely used: on the one hand they enable manipulations of microbial genetics, physiology and biochemistry to be accomplished with higher plant materials; whereas on the other hand, they prove a direct tool for the propagation of useful agricultural varieties. A major volume attempting a contemporary review of the field should reflect a fair measure of this excitement and potential. Indeed, there are some excellent and readable reviews in *Plant Cell, Tissue and Organ Culture* which capture interest and stimulate thinking. Several reviews of plant cell culture techniques

are particularly notable. These excellent gems are, however, set with uninspired efforts to make up this collection of thirty-five articles. Several of the reviews are either very poorly written or ramble from the declared topics.

The whole volume can be compared to that paragon of biological reviews, *The Bacteriophage Lambda*, published by Cold Spring Harbor Laboratories. One profound difference is immediately evident. Although the *Lambda* book seems to be a product of firm editorial control, this present book does not seem to have had such direction and, consequently, reads as if it were written by committee. Further, the *Lambda* book focuses on an organism, and thus, has a unifying theme, whereas this volume attempts to cover not only many organisms but also the entire complex phenomenology of plant cell, tissue and organ culture. Perhaps this is too much to ask of one book. We are left with the impression that the immediate details of the technology of *in vitro* plant culture overshadowed a coherent presentation of the underlying

biological principles. In a sense, the volume doesn't constitute a book (although bound as one) but a collection of reviews on *in vitro* plant culture, which could be the tissue culture chapters from books on specific crops, cytogenetics, development or other aspects of plant biology.

A closer look at a few of the chapters is instructive. Chapter 1 is called "Regeneration of Plants, Vegetative Propagation and Cloning". The authors of ten individual articles which comprise this chapter discuss many other aspects of plant cell and tissue culture besides these topics. A good number of them cover in elementary detail the very basics of plant cell culture, such as media composition and preparation of the explant; others attempt to cover all aspects of plant cell culture, including such items as haploids, mutagenesis, disease resistance and economics. The present chapter title is perhaps inappropriate and misleading, and could better be "Current Status of Cell and Tissue Culture with Regard to Selected Crops". This first chapter might have been organised around fundamental aspects of regeneration. What induces organogenesis and embryogenesis? What do we know and what do we need to know? What approaches are currently being taken to get answers to these questions? Then there could have been a final section on current applications of the *in vitro* techniques and further prospects. In organising the chapters by crops, the editors have permitted redundancy and inconsistency in the degree of detail.

Chapter 3, entitled "Cytology, Cytogenetics and Plant Breeding", doesn't

deal with plant breeding at all; that is, it doesn't give examples of breeding schemes or new varieties or individual plant breeders who utilise tissue culture techniques. There is also an inappropriate mixing of whole plant and tissue culture experiments. The reviews are typically a cataloguing of experiments, with little or no attempt to pull these findings together into a hypothesis (let alone, a theory!).

Chapter 4, "Protoplasts, Somatic Hybridisation and Genetic Engineering", contains very detailed reviews of the subjects it considers. In particular, each article tends to have full discussions of the experimental technique involved, although occasionally, at the expense of a critical evaluation of the implications of the data obtained. There is no mention of either recombinant DNA or crown gall—disappointing, since these are two very promising approaches to genetic engineering. Each article unfortunately contains small sections which repeat the material discussed as the main topic of another section.

Chapter 6, entitled "Cell Culture and Secondary Products", is very straightforward with three subsections. These include culture techniques, secondary products, and tissue culture and pharmacy. A nice addition to the extensive secondary products list in section two would have been the area of importance of these products. The author of section three was the only one to make a real effort to discuss the exciting range and importance of plant secondary products. This chapter contains a great deal of information which should be of value to

those contemplating, or presently involved in secondary product research, but may be a confusing compendium of chemicals to others. The excitement of the area—where it's been, where it is and where it's going—was not obvious.

Some positive suggestions may be in order. The editors might have written a reasonably in-depth introduction to each major section. This could have served the function of bringing loose ends together and pointing out unifying concepts. If the book is ever revised, as such a work might be, it could be offered in several smaller volumes, even in paperback. This would allow investigators to buy just those sections which are of most interest to them. In fact, each chapter could have been one paperback. The redundant sections would then have become useful, the price could have been cut considerably, and the material might have reached a wider market.

In spite of its deficits, *Plant Cell, Tissue and Organ Culture* will find its way into a great number of laboratories working with plant cell culture. It does contain a copious quantity of factual information and thus fills a need. It is a shame that the publishers have decided to fix the price so high, and that copyright laws restrict photocopying. A photocopy at one quarter the expense is attractive—but we don't want to introduce scientists into a life of crime!

Atomic collision theory

Potential Scattering in Atomic Physics. by P. G. Burke. Pp. viii + 138. (Plenum: New York and London, 1977). \$27.

ALTHOUGH many of the theoretical ideas underlying the scattering of electrons by atoms were developed in the 1930s, particularly by Sir Harrie Massey and his collaborators, it was not until the development of electronic computation in the early 1950s that really extensive calculations could be carried out to test these ideas. It was a happy chance that the start of Professor Burke's career (under Sir Harrie Massey at University College, London) coincided with this development, of which he took the greatest advantage. Now he is not only one of the leading authorities on the theory

of atomic collisions, but also on the complex techniques involved in the computation of cross-sections which are both of intrinsic interest and of practical importance in the theory of plasmas, of astrophysics and in parts of theoretical chemistry. With the author's reputation in mind, one turns to this little book with high hopes, which are not disappointed. Here is a marvellously lucid and concise account of the elementary parts of atomic collision theory admirably serving as an introduction to the subject.

The book starts with an account of scattering by short range spherically symmetrical potentials, which is then generalised to include long range Coulomb potentials and spin-dependent potentials. Following this basic material, elastic scattering of electrons by atoms or ions is discussed and it is shown how, at low energies, the effective range and quantum defect theories can be developed. This leads naturally into a discussion of resonance scattering

with a brief account of some of the analytical properties of the scattering matrix. Some of the most fruitful techniques for the many electron problem have been based on variational methods and these are discussed in some detail, together with the associated problem of finding bounds to the phase shifts. The book concludes with chapters on the Born series and its convergence, and on those approximations that have been developed for use at high energies, including the well known Glauber approximation.

Although much of this book could be read with profit by final year undergraduates, it will be of most use to those students who are starting research in atomic physics or quantum chemistry, for whom it will serve as an elegant introduction to the original literature and to the advanced treatises.

B. H. Bransden

B. H. Bransden is Professor of Theoretical Physics at the University of Durham, UK.

Crab biology

The Biology of Crabs. By G. F. Warner. Pp. xii+202. (Paul Elek: London, 1977.) £6.95.

It is no easy task to write a book about crabs which will both appeal to and be bought by a wide audience. One approach is to produce a short cheap book which will enter the undergraduate market as a supplement to more general texts, a second is to aim for a more definitive work which will become a necessary standby for every research worker involved with the Brachyura. Dr Warner has made a brave attempt to bridge this gap.

First, I must indulge in that measure of nit-picking required of a reviewer to prove that the book has been read. On p81, *Inarchus* should read *Inachus*, and on p139 *Metopaulus* should be *Metopaulias*. More seriously, on p121, $a > 1$ for positive allometry and $a < 1$ for negative allometry, and not the converse as is stated. Generally, however, the book is accurate, very well written, and complemented by a set of extremely clear diagrams which are either original or redrawn.

My main criticisms deal with sins of omission rather than of commission—with the balance of the material presented in relation to the book as a whole. Naturally the criticisms will reflect my own interests and prejudices, just as the content of the book reflects those of the author.

In the first chapter on anatomy and basic function, the stomach is discussed and illustrated at length, whereas the entire reproductive system is dismissed in a half-page of text. In the third chapter compound eye theory is considered in some detail without being related specifically to the Brachyura. In the chapter on rhythms, tidal and diurnal cycles are covered fully, but annual cycles of reproduction and moulting are glossed over—by no means all temperate crabs have synchronised annual breeding periods.

The chapters on life styles and food and feeding are fascinating but all too short, whereas that on social behaviour is particularly detailed in comparison. In chapter 8 on life histories some mention of how growth can be determined by Hiatt's method or by suture tags would be worth including, and a simple diagram would profitably replace most of the long verbal description of the mechanism of autotomy. The penulti-

mate chapter attempts to bring some order to the confused state of brachyuran phylogeny. I must personally disagree strongly with Glaessner's viewpoint, and emphasise that the affinity of the Raninidae and Tymolinae are with the primitive Brachyura, and that of the Oxystomata with the other advanced Brachyura.

There is sufficient background information in this book to make it intelligible to the non-specialist, and because of this it is certainly a useful source of facts and ideas for the undergraduate who wishes to seek examples of biological theories in action. The ecological diversity, yet basically conservative morphology, of the Brachyura makes them an excellent medium for this purpose. The book is of more limited use to the research worker because of the background content and the restricted length. Few aspects are dealt with in real depth, and the number of references is small in this context. But it is the only book on crab biology available in English. It is also a readable book, and will certainly provide a good introduction to the group.

Richard G. Hartnoll

Richard G. Hartnoll is Senior Lecturer in Marine Biology at the University of Liverpool, UK.

Defining the virus

The Virus: A History of the Concept. By Sally Smith Hughes. Pp. xix+140. (Heinemann Educational: London; Science History Publications: New York, 1977.) £3.90; \$6.95.

FIFTEEN years ago, it was relatively easy to define a virus. Since then, it has become increasingly difficult. The 1960s were the hey-day of the virion—that is, the definitive, observable infective particle of a virus. It was a circumscribed, compact, convenient entity and, for any one virus, once it had been described, the virion was essentially characterised.

Eighty years ago the subject was shrouded in confusion because of the lack of knowledge. Paradoxically, it has become more difficult again now, because of a plethora of knowledge. For example, the distinction between viral and cellular DNA in the DNA tumour viruses has become increasingly blurred, and, so far as the bacterial viruses are concerned, the plasmids have obstructed the once clear picture of phages as bacterial viruses.

The concept of the virion as the essential and definable stage in the

biology of any virus was not easily won, and the slow climb from confusion with the bacteria to the molecular biology of the 1960s makes an interesting story. Needless to say, it was not a smooth one, and it went by fits and starts rather than by steady progress. The 1890s were a watershed, when the agents of tobacco mosaic and foot-and-mouth disease were characterised as novel and even bizarre.

Dr Hughes spent three years as a historian in an academic department of virology, and her book records well the period leading up to the 1890s, and in particular the words and thoughts of Ivanovski and Beijerinck, their relative contributions to the subject, and something of how they lived, moved and had their being. (Who would have dreamed that Beijerinck's father was a tobacco-nist?) The story after the turn of the century is told somewhat more briefly, and supplemented by useful tables and appendices. The whole book is well produced and remarkably low-priced. One of its attractions is that most of the story can be read in the course of an evening. Strongly recommended.

A. P. Waterson

A. P. Waterson is Professor of Virology at the Royal Postgraduate Medical School, London, UK.

Ancient supernovae

The Historical Supernovae. By D. H. Clark and F. R. Stephenson. Pp. x + 233. (Pergamon: Oxford and New York, 1977.) Hardback £8.50; paperback £3.95.

THE history of astronomy is a history of man struggling with new ideas and painstakingly trying to make accurate observations of celestial objects. Ideas were easier and their reporting is more widespread; flat earths, geocentric systems, perfectly smooth and spherical moons and planets, crop up in many of the contemporary books and manuscripts. Reports of observations are rarer and less easy to decipher. Some examples are Eratosthenes's estimation of the size of the Earth, the measurement of the Earth-Moon distance by Aristarchus of Samos, and the catalogue of 1,080 stars made by Hipparchus which not only gave the celestial latitude and longitude of each star but also divided them into six magnitudes according to their brightness.

Legend has it that one of the factors that motivated Hipparchus to perform this task was the appearance of a nova in Scorpio in 134 BC. Interestingly, two of the greatest astronomers of the past millennium, Tycho Brahe and Johannes Kepler, were also fascinated by the new stars which appeared in AD 1572 and 1604. Novae, supernovae and supernovae remnants also seem to have fascinated David Clark of the Mullard Space Science Laboratory, University College, London, and Richard Stephenson of the Institute of Lunar and Planetary Sciences, University of Newcastle upon Tyne, and motivated them to write this book; we should be thankful they did. Their task was one of the more difficult tasks in the study of the history of astronomy, the careful and painstaking perusal of historical records for references to new stars.

The book is divided into twelve chapters. The first sets the scene and convinces the reader as to the reasons why supernovae are so important. Not only are they one of the more spectacular of stellar events but also their remnants, the ejecta of the explosion, are amongst the most unusual and exciting astrophysical phenomena. Supernovae are thought to be responsible for pulsars, black holes, runaway stars, extended sources of radio emission, beautiful expanding nebulous objects, galactic X-ray sources and possibly gravitational radiation. About one supernova occurs in our galaxy every 120 years, the high degree of obscuration cutting down the number observed from Earth. Luckily, observa-

tions of supernovae and their remnants in other galaxies has increased our knowledge of these objects enormously.

The second chapter reviews the historical sources used—Far Eastern histories and diaries (remarkably detailed records from Chinese professional astronomers/astrologers going back to about 200 BC), Arabic astrological works, medieval European monastic chronicles and post-Renaissance European scientific writings. Chapter three considers three types of new stars recognised by Far Eastern observers—the quest stars, rayed stars and sweeping stars, the latter two being tail-less and tailed comets. It also contains a catalogue of pre-telescope novae and supernovae complete with durations and approximate celestial galactic coordinates. Chapter four discusses the characteristics of supernovae remnants and lists the rem-

nants within 10 kpc of the Sun. Chapters 5 to 11 present a detailed discussion of the new stars of AD 185, 386, 393, 1006, 1181, 1572 and 1604, the prime supernovae candidates. The book ends with the authors' thoughts on the evolution of supernova remnants and a review of the possible effects a nearby supernova would have on the Earth and its environment.

At times, this book tends to exude the musty, mothbally smell of a doctoral thesis, an impression that is not helped by the fact that the book is typed, all 232 camera-ready pages of it. It is still, however, a fascinating account of these enigmatic early observations and is well worth reading.

David W. Hughes

David W. Hughes is Lecturer in Astronomy and Physics at the University of Sheffield, UK.

X-ray structural analysis

Structure Determination by X-Ray Crystallography. By M. C. F. Ladd and R. A. Palmer. Pp. 393. (Plenum: New York and London, 1977.) \$35.40.

THE jacket description claims this book to be "an indispensable guide for advanced undergraduates and beginning postgraduates", as well as being of interest to the large number of workers using crystallographic structure determination as a research tool. It is the first reasonably comprehensive textbook on the subject to be published for several years, and its emphasis differs somewhat from its companions.

The introductory chapters on crystal geometry are extremely thorough; the detailed analysis of space groups and their symbols, in particular, should prevent much of the confusion which a newcomer to the field experiences on first meeting them. The following chapter describes preliminary examination of crystals, and is less satisfactory in that it gives considerable space to techniques not frequently used (optical properties, indexing of oscillation photographs) yet only three-and-half pages to Weissenberg and precession methods, one or both of which is used in virtually every structure determination. There is, furthermore, no mention of the determination of crystal system and unit cell dimensions from Weissenberg photographs.

Chapter 4 derives structure factor equations from first principles; as throughout the book, the derivations

are clearly expressed and attractively presented, and the worked examples (particular space groups, systematic absences) provide considerable illumination of the principles involved.

The detailed methods of X-ray structure analysis are introduced gently and relatively early via simple (but real) examples involving consideration only of special positions; it is doubtless encouraging to the beginner to see 'real' structure determinations before considering more complex topics such as Fourier series and Patterson functions. These are introduced in chapter 6, again clearly derived and with several detailed examples of the application of Patterson methods, leading naturally to a discussion of heavy atom methods and difference syntheses.

The major disappointment is the relegation of direct methods to a chapter headed "Some Further Topics". In recent years, many advances have been made in the theory and practice of direct methods, and yet no material is presented which is not in Stout and Jensen's *X-Ray Structure Determination* (Macmillan, 1968). Some mention should have been made of non-centrosymmetric direct methods and the MULTAN philosophy, at the very least.

One might disagree with the authors' choice of material and emphasis (which they defend in the Preface), but one cannot criticise the quality of presentation. It must be asked, however, whether this book represents any substantial advance on other (cheaper) books already available on the subject; regrettably, it does not.

P. G. Jones

P. G. Jones is Lecturer in the University Chemical Laboratories, Cambridge, UK.

obituary

W. W. Bishop

DR. WALTER WILLIAM BISHOP, Head of the Department of Geology at Queen Mary College, University of London, died suddenly at his home on 19 February 1977, at the age of 45.

A native son of Birmingham, he graduated from the University there in 1952 with an honours degree in geography followed by a Certificate in Education. However, his interests turned towards geology and it was in this field that he received his Ph.D. degree at Birmingham in 1956. He went immediately to Africa as geologist with the Uganda Geological Survey and, through contacts with E. J. Wayland and L. S. B. Leakey, became involved with studies of Pleistocene deposits and the geomorphological evolution of the region.

By 1959 he had demonstrated the natural origin of the supposed "Kafuan" culture and provided evidence for morphological and tectonic control of the events that had led to the erection of a rigid climatic framework that now seemed insupportable. The fossil-bearing Miocene sediments also attracted his attention and his first African paper was a brief account of Miocene mammals from Napak. Further field work in Uganda and Kenya later led him to realise the important genetic relationships that existed between the Miocene fossil deposits and the volcanic cones throughout the region.

Thus, within three years of his arrival, was established the pattern of his many important contributions on the stratigraphy, geomorphology and volcanics of the Tertiary and Quaternary in East Africa, as well as his fruitful association with archaeologists, anthropologists and palaeontologists concerned with mammalian and hominoid evolution.

In 1959 he went to the University of Glasgow as Assistant Lecturer in Geology and Assistant Curator at the Hunterian Museum, but after three years returned to East Africa as Director of the Uganda Museum in Kampala and Lecturer in Geology at Makerere College, University of East Africa. These years were very productive and Bill Bishop soon became the recognised authority on the Tertiary and Quaternary of the region. At the Museum he was responsible for several new developments, such as the establishment of a Museum Education

Service. He organised a number of expeditions, including the Baker Centenary Expedition (1963) to study the geomorphological evolution of the Lake Albert rift valley, which led to a new picture of the stratigraphy and to important fossil collections from the Pliocene-Pleistocene Kaiso Beds.

The prospect of a teaching position tempted him back to London in 1965 as Lecturer in Geology at Bedford College, where Professor Basil King was already interested in research on the volcanics of the rift valley and directed the East Africa Geological Research Unit. This unit undertook responsibility for systematic geological mapping in the Lake Baringo basin, where important sedimentary deposits were found sandwiched within a long volcanic sequence; these beds provided valuable fossil material bridging a former gap between the middle Miocene and the late Pliocene. Radiometric dating was applied to the entire Miocene succession, thus establishing for the first time a good chronology for the faunas.

After moving to Queen Mary College in 1974, Professor Bishop continued his East African field work, partly in association with Richard Leakey, but also began work in Pakistan where a group from Yale University was re-examining the Miocene-Pliocene Siwalik sediments and their critical hominoid fossils. He was invited to become Director of the Peabody Museum at Yale and his death occurred only a few months before he was due to take up this appointment. Not long before he had been honoured by the award of the Prestwich Medal of the Geological Society of London in recognition of the outstanding contributions that had made him "a world leader in the very active field of African geology."

Always a co-operative, enthusiastic and helpful person, Bill Bishop was deeply involved in local, national and international bodies ranging from student societies to the Presidency of the INQUA Sub-Commission for Quaternary Stratigraphy of Africa. He served the Geological Society of London as a Council member, as its Secretary, and as Scientific Editor of the *Journal*, doing a great deal to build up both the Society and its publication. He was joint organiser of two symposia sponsored by the Wenner-Gren Foundation for Anthropological Research and edited the two books that have

become standard references for the time scale of hominoid evolution. In 1975 he organised a highly successful three day symposium on a similar theme for the Geological Society of London, as yet unpublished.

Dr Bishop was a lively and attractive speaker and was guest lecturer at many institutions. At meetings, his tact and insight smoothed over potential conflicts and his humour was infectious. His performances in amateur dramatics and his admirable voice in light opera will long be remembered, as well as the witty ditties with which he sometimes enlivened scientific meetings. His death is not only a great loss to science but also a severe personal loss to his many friends and colleagues throughout the world. His happy family life with his wife and two sons did much to sustain him in his busy existence and his love of natural history remains imprinted in them as his science does in his students and his colleagues.

H. B. S Cooke

J. A. V. Butler

JOHN ALFRED VALENTINE BUTLER, F.R.S., Emeritus Professor of Physical Chemistry at the University of London, died on 16th July after a short illness.

'J.A.V.', as his friends knew him, was born on St. Valentine's day in 1899. His early education was at Cheltenham Grammar School, and he took his first degree in chemistry at Birmingham University. After a short stay at the University College of Swansea he spent 12 years as a lecturer at the University of Edinburgh. Although he was a physical chemist, we know that during this period he came into contact with Edgar Stedman who, in the late thirties, was beginning his work on the composition of the cell nucleus. From the few comments we heard J.A.V. make about his relationship with Edgar Stedman at that time, we gathered that it was not always harmonious. Nevertheless an obvious interest in the chemistry of the cell nucleus was planted at that time, and was to emerge later.

In 1939 a Rockefeller fellowship took him to the U.S.A. where he also served as an executive officer in the British Commonwealth Scientific Office in Washington.

In 1946 he returned to England to

work at the Courtauld Institute of Biochemistry in London for three years, and in 1949 came to the Chester Beatty Research Institute to apply his physical chemical knowledge and techniques to the study of DNA. This began an interesting and exciting 17 years, during which he studied many aspects of the chemistry of the components of the cell nucleus.

It was in 1953 that I first met J.A.V., and being a very junior member of the technical staff at that time I had little to do with him in an official capacity. However, within six months he was telling me in considerable detail why my geraniums were dying, and the need for repotting them at frequent intervals. Although I believe he was basically a shy man, he was friendly with all members of his staff, and never hesitated to allow the students a day off for the Varsity Rugby match at Twickenham.

He will be remembered also, I am sure, by his friends at the Institute, for his absent-mindedness. I have seen him return from an academic board meeting with two hats, one on his head and one in his hand, hotly pursued by the rightful owner of the second hat. On another occasion, deep in conversation with a colleague in a café, he complained about not receiving any change, only to find it in his coffee when he stirred it!

The stories about J.A.V. are legion. His lack of pens and pencils, the gunfight he caused in Chicago by losing his brief-case, and his very, very long pauses on the telephone before he answered "Butler here". He was in all ways the epitome of the "absent-minded professor".

We will also remember well his method of crossing the Fulham Road. Head down, deep in thought, shoulders slightly bent, straight across, ignoring all traffic. A screech of car brakes was often the sign that J.A.V. was crossing the road.

He was however, clear and precise about his research. Although he began by applying his knowledge of physical chemistry to the structure of DNA, he soon became interested in the wider aspects of DNA control and his interests lead him into the fields of DNA synthesis, RNA synthesis and the functions of the chromosomal proteins. This was, of course, in the fifties when molecular biology was in its infancy, and most people chose to forget that DNA was associated with an equal amount of protein.

He felt that the best strategic approach to the cancer problem was to understand the fundamental aspects of gene control and he directed his department to this end. However, he was keenly aware that this was a long term

approach and once confided to me that he was sad we could do so little of immediate value.

Apart from his work within the Institute, his scientific interests were wide and varied. He edited *Progress in Biophysics and Molecular Biology* for over 25 years and his publications, apart from his research work, varied from a text book on chemical thermodynamics to a very successful series of books, written for the layman, on various aspects of cell and molecular biology.

He was appointed to the newly-established chair of Physical Chemistry at the Institute in 1952, and was elected a Fellow of the Royal Society in 1956.

After his retirement in 1966 he still took an active interest in the work and was often to be seen at scientific meetings. He frequently called in to see us and to hear about the latest work. His last visit was early this year, when true to form he left his brief-case in my room, fortunately remembering it before he left the building.

He was widely read, keenly interested in the arts and an amateur painter of some merit.

He married Margaret Lois Hope in 1929, and as all his friends who visited his home knew well, he had a very happy and contented domestic life. His three children, two sons and one daughter, all followed his lead and have made careers in various other scientific disciplines. *E. W. Johns*

F. H. Ludlam

F. H. LUDLAM, Professor of Meteorology and Head of the Atmospheric Physics Group at Imperial College, London, died on 3 June 1977 aged 57 years. Frank Ludlam studied clouds. His descriptions of the movement of air and water vapour and rain through clouds were so intense and graphic that one began to suspect that he had some supernatural power to actually identify himself with a cloud.

He saw so much. He would come into a lecture with perhaps 20 slides then spend all his time talking about the first, frequently drawing back from removing it because some new feature had just caught his attention.

Having made fundamental contributions to the microphysics of clouds during the 1940's while working at the Meteorological Office, he moved to Imperial College and away from the study of the details of processes towards the study of the organisation and dynamical structure of clouds. This philosophy culminated in his now

classical description of the motion of air in severe thunderstorms. Like all grand ideas this one could, in retrospect, have been seen coming for years, but Ludlam had it. He discarded what he called 'the haystack theories' of storms. These were illustrated by diagrams, and thinking, with arrows all over the place. He replaced it by a streamline theory showing where the air and water came from and where it went to. He took a certain delight in the fact that, working on a tiny budget, he made a very satisfying advance in a subject of great economic importance.

Subsequently his interest shifted progressively to phenomena of larger scale. For his inaugural lecture in 1966 he showed that weather systems could be seen in a new perspective by examining them relative to axes moving with the system: again almost identifying himself with the phenomenon. This was his way of using the abstract concepts of pattern movement as distinct from pattern development developed by his penetrating contemporary, Eady. But whereas Eady's concepts were based on distinction of mechanism and arose from mathematical elegance and clarity, Ludlam made them lead to pictorial and functional beauty.

No man showed better the false distinction between artist and scientist. To him good science made a pleasing picture. He delighted in the impish gesture. Few present at a lecture to the Royal Meteorological Society (on three-dimensional data analysis) will forget the impact made when he projected a slide of a Rodin nude (very female) in the middle of a masterly description of the techniques of synoptic analysis.

In his magnum opus entitled *Cloud Physics* to be published by the Pennsylvania State University Press, he summarises his views on atmospheric phenomena from a few microns in scale to 40,000 km. He was concerned with the notion that conventional physicists, wedded to the controlled experiment, did not understand the essence of meteorology as he saw it. What he did see was an immensely elaborate system with complex feedback. The essence was the feedback and the uncontrollability of the meteorological experiment. He was the privileged on-looker. He even took lightly some of his beautiful and fundamental work on cloud microphysics and said it did not really matter if it were wrong: the atmosphere would find some way of fulfilling a more over-riding purpose whatever the details of the processes.

Such an integrating philosophy is likely to be fundamental for the study of complex systems like the atmosphere and we are privileged to have had so talented an exponent of it.

John Green

what's new—spectrometers

In addition to the regular Newly on the Market section in *Nature*, special features on a particular type of laboratory equipment or instrumentation will be published in this and forthcoming issues.

The purpose of a special feature is not to give listings of every item in the range of the manufacturers mentioned but to take a variety of equipment of interest in that feature area and give an idea of what kinds of instruments are available and from whom. There is a Reader Enquiry Coupon facing the inside back page.

Anaspec introduce a completely new type of microspectrophotometer, which will record absorption, emission, scattered or fluorescence spectra of any object capable of being viewed in a microscope. This revolutionary system is a miniaturised double monochromator spectrophotometer, that can be attached to a standard trinocular microscope, such that the only limit to sample size is the actual microscope image magnifying. The system is manufactured in the U.S.A. by Nanometrics Inc. and consists of a number of separate modules which can be purchased separately, according to need or application. These modules include microscope, spectrophotometer, wave length programme, recorder and a micro computer for more complex analysis. Applications include almost every area of life sciences, microbiology, geology, forensic science, chemistry and electronics. For example, the system can measure the absorption spectrum of a single chromophore in a cell, or in forensic studies can plot a spectrum from a part of a single fibre. In addition the system is ideally suited to measuring semi-conductor film thickness in an area as small as 0.001 mm.

Although NanoSpec/10 is designed primarily for micro work, it also has application to large area analysis on the same specimen, *in situ*, where before-and-after differences over a wavelength range caused by chemical change, migration, photosynthesis, chromatography or other effects can be computed and recorded. This is not possible with conventional instruments. Any specimen which can fit onto the

microscope stage can be studied in this manner.

Circle No. 45 on Reader Enquiry Card **KeveX** present several new systems. The nuclear fuel analyser is a way of achieving rapid, non-destructive and automatic elemental analysis of reactor fuel elements with a new computerised X-ray energy spectrometer (XES) system. Two solid state silicon detectors are multiplexed to double the spectrometer's count rate capability. 100% element certification is achieved on the order of 10 s per nuclear fuel pellet. The system is completely automatic with the computer selecting and controlling: X-ray tube voltage and current, secondary targets and filters, specimen transport, acquire and analyse data and sample advance. Other applications include: effluent analysis, pollution analysis and accurate accountability of special nuclear materials. Little or no sample preparation is required. The system can be employed as a materials monitor in response to the challenge posed by nuclear proliferation. The Ultra-Trace has the

technology. This new product will provide process control chemists, the pharmaceutical industry and medical researchers with high speed, high dynamic range analytical capabilities. Quantitative element analysis of thin films and surface layers (e.g., oxides) are achieved with a new product and a new surface analysis technique. A new product is the KeveX Alpha-X, and the new surface analysis technique uses 5-MeV α particle induced X-ray emissions. Windowless detector-cryostats and radioisotope source-collimator subsystems are combined to yield heretofore unprecedented analytical performance. Rapid non-destructive quantitative analysis of elements of atomic number 6 (carbon) and up of surface layers are now possible using the KeveX Alpha-X. For example, carbon and oxide layers of less than 15 Å can be detected. Alpha-X spectrometers appear in two configurations: (1) integrated stand-alone systems and (2) attachment or accessory surface analysers. The accessory version of Alpha-X may be attached to existing Auger/ESCA type surface analysis chambers to yield complementary information. The stand-alone system is capable of both surface and bulk material analysis.

Circle No. 46 on Reader Enquiry Card

Instrumentation Laboratory (UK) Ltd introduces the IL 751 dual-channel double-beam atomic absorption spectrophotometer with built-in microcomputer. The new IL 751 Atomic Absorption Spectrophotometer is a dual-channel double-beam instrument which includes a microcomputer to make all the required computations. Each channel contains a full-size 330-mm monochromator, and both channels can operate with deuterium arc background correction. The two-channel system can produce great improvements in atomic absorption analysis, when used in either of its two main modes: (1) Doubled analytical speed. The IL 751 can analyse samples for two elements at one time. Conventional instruments can only determine one element at a time. (2) Greatly improved analytical accuracy and simplified sample preparation. In the internal standard mode, the absorbance of the element being determined is compared to that of an element having a known

KeveX Alpha-X system

unique ability to analyse many ultra-trace elements simultaneously, non-destructively and rapidly. The minimum detection limits for elements of atomic number 23 through 92 are on the order of 50–100 pg. Minimum detection limits for elements of atomic number 9 through 22 are somewhat higher. Ultra-Trace uses new and advanced X-ray energy spectrometry

concentration. This technique overcomes many matrix effects, such as sample viscosity or solution temperature, and minimises the effects of errors in pipetting or dilution. The IL 751 includes a microcomputer which performs all the calculations that are useful for atomic absorption data handling. Among these are linearisation of the analytical curves in both channels, using two, three, four, or five standards; readout in concentra-

IL (UK) Ltd 751

tion in single-channel, dual-channel, or internal standard modes; peak height and peak area measurements; and provision of statistics including the mean, standard deviation, and RSD values. There are two special features: one is a keyboard-lock mode, which secures a program from disruption by an unskilled operator or curious passer-by. The other is a standby mode, in which the computer retains its calibration program even when the instrument is switched off. The IL 751 also contains a built-in alpha-numeric printer-sequencer, which identifies the results in addition to printing them out.

Circle No. 47 on Reader Enquiry Card

Techmation announce a new plasma emission spectrometer. A new single element plasma emission spectrometer, Spectraspan IV, will be available at a price normally associated with atomic absorption units. The highly versatile Spectraspan IV, developed by SMI, can perform quantitative and qualitative analyses of trace concentrations including refractories and some non-metals. It has a high sensitivity even in the presence of complex matrix solutions with solids contents as high as 20%. The high intensity excitation source is a d.c. argon plasma which operates at low power but produces temperatures as high as 10,000 K. As with the Spectraspan III Multi-element analyser, an integral microprocessor not only increases the efficiency of the system but allows routine checks of instrument performance. Plasma emission spectrometry has applications to a wide variety of environmental samples of unknown or varying composition; including trace elements in storm drain outfalls, sewage, sediments, soil, animal tissue, oil, plastics, sea water (including

measurements of mercury concentration as low as 0.15 p.p.b.), distilled water, brackish water, waste from plating baths, trace metal impurities in alloys and total phosphorus in storm drains.

Circle No. 48 on Reader Enquiry Card

Perkin-Elmer announces the first microcomputer-based UV-VIS-NIR spectrophotometer. Designed to meet the highest possible standards, the Model 340 offers three important benefits to the user. The first is ease of operation, the second is high performance enabling highly accurate photometric determinations and the third is versatility in sample handling, obtained through convenient instrumental operating conditions and well designed accessories. The heart of the Model 340 is a microprocessor which monitors all instrumental functions. It controls source and filter changes, the stepper motor monochromator drive, the integral X-Y recorder, zero and 100%T calibrations, response times, auto zero and automatic baseline correction, etc. Covering the range 190-260 nm with a resolution of 0.15 nm, the Model 340's double monochromator reduces stray light to 0.0002%T at 300 nm; the microprocessor enables a baseline flatness of $\pm 0.001A$ in the UV/VIS region and 0.002A in the NIR region, to be achieved. A wide variety of sample handling accessories are available. The Model 340 can be equipped with long path cell holders, thermostatted cell holders and flow-cells. A complete line of integrating spheres enable precise measurements on solid and turbid samples over the entire wavelength range. A new addition to the 97 Series of IR Spectrophotometers, the Model 597, has been designed to meet the

Perkin-Elmer Model 340

growing need for instrumentation providing reliability, accuracy, versatility and simplicity of operation at a moderate cost. A high energy double beam optical null spectrophotometer, the Model 597 features an extended wavelength range of 4000 cm^{-1} to 200 cm^{-1} . Four scan speeds are offered,

three slit programmes and a time drive facility allowing transmission changes with time to be recorded on the instruments own Flowchart recorder. It is compatible with Perkin-Elmer's new Infrared Multisampler which allows up to thirty samples to be run completely automatically. For analyses in the region 250 cm^{-1} to 200 cm^{-1} , where dry air or nitrogen purging is recommended, the sample compartment has been fitted with a sliding lid. The unique check gain control allows the gain to be accurately and reproducibly set, even when the lid is closed and a sample is in the beam.

Perkin-Elmer Model 597

The double beam, UV-Vis Spectrophotometer, the Model 556, is ideally suited for applications involving turbid samples, mixture analysis and many other biochemical and industrial applications. Two separate diffraction grating monochromators, with independent selection of wavelength, produce the sample and reference beams which pass along identical paths through the sample cell. To record the spectrum of a turbid sample where no reference solution exists, one monochromator can be fixed and the other set to scan. Alternatively, the two monochromators can be fixed a few nanometers apart and both scanned together to record the first derivative of a spectrum. A simple push button action converts to double beam operation with both sample and reference beams taken from one monochromator. Regular difference spectra can then be recorded with a performance level equal to many dedicated double-beam instruments. The instrument's XY recorder provides recording of the complete spectra on precalibrated chart paper, and allows step-wise expansion and concentration. Charts are conveniently stored on a pull-out roll; automatic pen lift and scan synchronisation are provided. Superimposed repetitive scanning is possible between pre-set limits using controls that read out directly in wavelength. Spectra can be recorded at eight scan speeds (up to $1,200\text{ mm min}^{-1}$) with automatic selection in reverse.

Circle No. 49 on Reader Enquiry Card

The Schoeffel Instrument Corporation introduces a new Universal High Sensitivity Spectrophotometer, HS 870, which accepts both microliter and milliliter type cuvettes to enable the researcher the option of using the instrument as a continuously variable wavelength monitor for HPLC or to do standard spectrophotometric analysis. This two-in-one concept saves the experimenter both money and valuable space. This HS 870 uses a true double-beam approach which assures a superior signal-to-noise ratio and maximum stability. The unit features a digital data display as well as three switchable modes of operation permitting measurement of transmission, absorbance, and concentration. An automatic gain control (over two orders of magnitude) and a zero suppression (total range greater than 2 A.U. or 120%T) are standard. A BCD output for computer interfacing is optionally available. The incorporated continuously variable monochromator with wide wavelength range (190–700 nm) enables the user to select the maximum absorbance of the compound of interest. This unit is modular in design with an emphasis on practicality.

Circle No. 50 on Reader Enquiry Card

Varian announce a new, moderately priced ultraviolet-visible spectrophotometer, featuring a double-pass monochromator and exceptional photometric linearity. The Varian Cary Model 219 UV-Visible Spectrophotometer has a resolution of less than 0.07 nm and a stray light characteristic of less than 0.002% at 220 nm. Photometric linearity is 0.0016 at 1A to 0.03 at 3.0A. Ease of operation is enhanced by the instrument's wavelength coupled recorder, automatic 0%T setting, automatic source changing, automatic baseline correction and automatic repetitive scanning over the entire 185–875 nm wavelength range. Other features are a five-digit absorbance readout for high-precision measurements, expanded recorder ranges for instrument versatility and a large sample compartment preplanned for current or future accessory additions. Modes of operation include single beam for wavelength accuracy checks and double beam for normal absorptiometric applications. Either auto-slit (constant noise) or auto gain (constant resolution) can be selected when operating in the double beam mode. A beam interchange control on the front panel electrically reverses the function of the sample and reference beams.

Philips present a variety of spectrometers and ancillary equipment. The PW 1600 is a simultaneous X-ray spectrometer fitted with a 12-position sample changer and fast printer. This versatile system—which permits the analysis of up to 28 elements in under a minute—is designed to meet the demand for high volume quality control analyses in the metal, mining, cement and similar industries. There is a new 3 kW X-ray generator—the PW 1730—together with vertical and horizontal goniometers, a tabletop X-ray generator, two Debye Scherrer cameras with advanced safety features, a radiation alarm monitor specially suitable for monitoring 'soft' X-rays and the latest generation of Philips X-ray tubes. The PW 1730, can be used for single tube and

Philips PW 1730 system

two tube sequential or simultaneous operation. High voltage is variable between 20 and 60 kV and tube current between 10 and 80 mA. Stability of kV and mA is 0.002% per 1% mains voltage variation and temperature drift is 0.002% per 1 °C ambient. Maximum output power is 3 kW. To save space and cost the X-ray programming and control electronics can be housed in the generator cabinet. Where additional modules are required—such as in highly automated systems—these can be housed in the optional PW 1735 Extension Console which also includes provision to mount a second X-ray diffraction tube tower. With the many options offered, the PW 1730 can be easily upgraded as needs change and larger systems are required. For example, a simultaneous control unit allows two X-ray diffraction tubes or one X-ray diffraction and one X-ray spectrometry tube to be used simultaneously. A high voltage switch enables two X-ray tubes to be used sequentially. These accessories

eliminate the need for a second generator in many applications—a very significant cost saving. High voltage, filament supplies, safety devices and cooling water are all automatically controlled for both tubes when either a high voltage switch or the simultaneous control unit is fitted. An additional overload protection unit is also available to protect tube(s) and generator during single or two tube sequential or simultaneous operation. The PV 8350 emission spectrometer is a direct reading vacuum spectrometer providing fast quantitative measurements at a cost that makes it a practical quality control tool for even relatively small steelworks and foundries. Typically it determines up to 20 elements simultaneously, including carbon, sulphur, phosphorus and boron. The EXAM 6 energy-dispersive X-ray fluorescence system is for simultaneous elemental analysis in such fields as metallurgy, ceramics, cement, food and forensic studies.

Circle No. 52 on Reader Enquiry Card

Glen Creston Instruments Ltd present the Spex Fluorolog Spectrofluorometer and the Ramalog 5M/6M Laser Raman Spectrometers. In addition to the standard emission and ratio emission measurement, it is possible to measure transmittance, absorbance and partial fluorescence efficiency without changing the configuration of the Fluorolog. In the ratio emission (or emittance) mode, excitation spectra are corrected automatically by the reference detector. Emission and higher order corrections are possible with the computerised counterpart of the instrument. This incorporates the necessary computer and software. A phosphorimetry attachment is available as well as many other accessories such as sample heater/cooler, variable temperature accessory and polarisation kit. The Spex Fluorolog and its computerised counterpart, the Fluorocomp, are new research systems and any type of luminescence can be measured by the Fluorolog. Its modularity enables change of the source, the detector, the sample compartment, the electronics and the optics. So modified, the system can handle almost any luminescence measurement, at any temperature, in any atmosphere, in a magnetic field and under experimental conditions dictated by the effect sought. A gated detection system of photon counting is one of the Fluorolog features, giving numerous advantages accruing from counting the actual photons impinging on the PMT cathode instead of measuring the resulting direct current including a significantly improved signal

noise ratio. Either a 150 or 450 W xenon arc can be plugged in. Normally operated cw, the lamp can be pulsed with a special phosphorimetry attachment; then the pulse rate can be varied up to 60 Hz and the sampling time from 1 μ s to 10 ms. To maintain focus on a sample regardless of the excitation wavelength, and to assure maximum collection of light from the lamp, a large, off-axis ellipsoidal mirror was selected. The Fluorolog has been designed so that it can operate with a computer controlling both wavelength scanning and data gathering. A system incorporating the necessary computer and software is the Fluorocomp. This system not only acts as a data collection device, but also makes decisions in real time to change such parameters as integration time, scaling, and signal-to-noise (total number of photon counts). Subroutines already developed or being written include: repeat scanning of emission or excitation spectra; storage and retrieval of data in a floppy disc mass storage system. The Ramalog 5M/6M Laser Raman Spectrometers are the latest Spex laser Raman systems available.

Oriel introduce a CO₂ laser spectrum analyser which is a unique grating spectroscopy simultaneously displaying all the lasing transitions of a CO₂ laser. It is calibrated both in wavelength and rotational line designation to permit easy identification of 140 possible laser transitions between 9.1 and 11.3 μ m. These transitions are visually displayed through the use of an ultraviolet excited thermal sensitive screen which darkens in the area struck by the IR laser beam. The screen has a response time of 0.25 s and permits the instrument to resolve all the CO₂ rotational lines. The model 16 series is light, portable and can easily be introduced into laboratory setups.

Circle No. 54 on Reader Enquiry Card

Pye Unicam Ltd present a wide variety of spectrometers and associated equipment. The PW 1600 simultaneous X-ray spectrometer is a new multi-channel X-ray spectrometer where the total time for analysis of low or high alloy steel is 20 s, inclusive of loading the sample via the air lock and exclusive print-out of the results. High accuracy is obtained through an integrated computer with advanced software that enables the user to take full advantage of the recent achievement in the field of inter-element corrections. For this purpose tables of influence coefficients can be supplied with the instrument to suit the user's

requirements. In this way the calibration of such instruments to analyse samples with a wide range of compositions has become a matter taking only one or two days and 6 to 30 standards. In the past such wide range calibration programs have sometimes required several weeks of work and up to 200 standards. The instrument has a high stability as is required for routine operation with a minimum of recalibration time needed. A compensation has only to be made for long term drift and this is done once every 8 hs. The drift correction is made for each individual analysing channel by means of a multi-element monitor situated in the 10-position sample turret in the spectrometer. The correction is on operator's command and is computer controlled. A combination of curved and flat crystals together with a new ground cathode end window X-ray tube and advanced measuring electronics gives the PW 1600 extremely short analysis times with high spectral resolution. The PV8350 direct reading emission spectrometer provides rapid analyses at relatively low cost. The concentrations of up to 20 elements, including carbon, sulphur and phosphorus, can be determined simultaneously in materials such as steel, iron, non-ferrous alloys, etc. The instrument is designed to respond reliably to the needs of foundries and steel plants for continuous production control analyses. Outstanding analytical performance and stability are achieved

Pye Unicam SP1050

by a combination of advanced optical and electronic design. The high resolving power, blazed grating optics of one metre radius cover the wavelength range 1,770 Å to 4,100 Å in the first order at a reciprocal dispersion of 4.63 Å mm⁻¹. The instrument's 50 Hz monoalternance source unit generates a special type of discharge of improved reproducibility. Modular electronics and freedom to choose the most appropriate measurement lines in each case, enable a PV8350 spectrometer to be tailor-made to match individual analytical requirements. Running under automatic control of a number of preselected programmes, the system

is simple to operate, and its excitation stand accommodates samples of a wide range of dimensions. The electronics can provide an automatic printout of the measured intensity values by a digital printer. There are alternative electronics for teletype printout and adaptation to a computer controlled emission spectrometer with direct readout in concentration. Other modules which can be incorporated within the standard spectrometer unit include a source unit operating at 500 Hz and offering the ultimate in analysis speed. Infrared spectrometers are being used in every type of industrial and scientific environment. The vast majority of applications require a fast, robust instrument combining flexibility, high performance and simplicity of use. All of these qualities can be found in a newly developed Double Beam infrared Spectrophotometer, the SP1050. The SP1050 has a linear wavenumber scale of 600–4,000 cm⁻¹, nichrome strip source, double beam optics and grating monochromator. It has solid state electronic systems and an integral strip chart recorder. The reliability and sensitivity of the company's IR50 Infrared Detector is now well proven and this successful detector has been incorporated into the design of the SP1050.

Circle No. 55 on Reader Enquiry Card

Zeiss introduces the new DM 4 Double-Beam Spectrophotometer. The Zeiss DM 4 is the latest addition to the Zeiss line of spectrophotometers that meets practically all requirements in absorption spectrophotometry for the ultra violet, visible and near infrared regions. This makes it a very efficient instrument in any analytical laboratory, for research in the material and life sciences, as well as for routine analyses wherever accurate and reproducible results are required. The great advantage of the DM 4 is that it is equally convenient to operate for rapid routine concentration analysis and kinetics as it is when it's used as a scanning ratio recording instrument for qualitative determinations. An exceptionally large and readily accessible sample compartment contains a 6-position sample changer which can be automated. Among its many features are automatic lamp switch-over, fool-proof push-button operation, precision Zeiss grating monochromator, and unique wave-length scan. The DM 4 has a spectral range from 195 to 850 nm, an absorbance range from -0.3 to 2.5 A, a concentration range from 0 to 10,000. It requires no more than 0.3 ml sample volume. Digital and analog outputs are provided.

announcements

Appointments

Professor S. T. Butler, to Head of the Nuclear Science and Technology Branch in the Australian Atomic Energy Commission, in charge of the AAEC Research Establishment at Lucas Heights, near Sydney.

Dame Kathleen Ollerenshaw, DBE, to succeed His Royal Highness The Duke of Edinburgh, KG, KT, as President of the Institute of Mathematics and its Applications on 1 January 1978. She is currently a Vice-President.

Dr A. E. Stuart, to Professor of Pathology, University of Newcastle-upon-Tyne, from 1 January 1978, and also as Head of the Department of Pathology for a period of five years from 1 January 1978. Dr Stuart succeeds Professor A. G. Heppleston.

Awards

The Dr W. Elenbaas prize for 1977 has been awarded to the British chemist **A. H. McKeag**, in recognition of his work in the field of luminescent materials.

Two Technology Writers' Awards, sponsored by ITT Business Systems under the auspices of the Association of British Science Writers, will be awarded for work published between 1 January and 31 December 1977. One will be for work published in professional periodicals, trade and technical magazines, or national and regional newspapers, the other for material broadcast on radio or television. Both prizes will be £1,000 cash and £500 for travel or equipment. All entries are by submission (to J. Anstiss, MPR Ltd, 293 Gray's Inn Road, London WC1, UK), and it is hoped to announce the winners in February 1978.

Meetings

24–26 October, **ASTM Symposium on Erosion: Prevention and Useful Applications**, Vail, Colorado (L. E. Burgess, ASTM, 1916 Race Street, Philadelphia, Pennsylvania 19103).

28 November–1 December, **International Conference on Optimisation of Sodium-cooled Fast Reactors**, London (British Nuclear Energy Society, 1–7 Great George Street, London SW1, UK).

29–30 November, **International Conference on the Future of Natural Fibres**, Manchester (J. K. Jackson, Shirley Institute, Didsbury, Manchester, UK).

30 November–2 December, **Conference on New Developments in Automatic Testing**, Brighton (The Institution of Electrical Engineers, Savoy Place, London, UK).

Person to Person

Exchange 2-bedroom furnished house in La Jolla, California, for flat in London, July–September 1978 to September 1979. Contact M. Friedkin, University of California San Diego, M-001, La Jolla, California, 92093.

Exchange 3-bedroom furnished house in San Francisco near UC Medical Center for similar in or near Central London for one year from July 1978. Contact H. E. Varmus, 956 Ashbury Street, San Francisco, California 94117.

Observations welcome from recent work in the field of increasing crop yields using an electrostatic field. The last reference I have, after Professor Lemstrom (1904), and Sir Oliver Lodge, is J. E. Newman, who conducted trials near Pershore, England, and reported increases in wheat yields of up to 20%, and also potato yield increases in experiments in Dumfries. (See Standard Handbook for Electrical Engineers, 5th edn, McGraw Hill). The work ceased about 1917. Contact A. F. Stobart, Manor Farm, Claydon, Banbury, Oxford, UK.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

3 December, **Public Educational Forum, 'The Recombinant DNA Controversy: Public Policy at the Frontier of Knowledge'**, San Francisco (J. Stubbs, Chair, Department of Cell and Molecular Biology, San Francisco State University, 1600 Holloway Avenue, San Francisco, California 94132).

5–7 December, **International Symposium on Mechanisms of Oxidising Enzymes**, La Paz, Mexico (Professor R. N. Ondarza, Consejo Nacional de Ciencia y Tecnología Insurgentes Sur 1677–10° Piso, Mexico 20, DF Mexico). 5–9 December, **1977 Fall Meeting of the American Geophysical Union**, San Francisco (Meetings, AGU, 1909 K Street, NW, Washington, DC 20006, USA).

5–9 December, **International Conference on Radiation Measurement**, Atlanta (J. H. Kane, Special Assistant for Conferences, Energy Research and Development Administration, Washington, DC 20542).

6–8 December, **Symposium on Applications of Electroanalytical Sensors**, London (Sira Institute Ltd, South Hill, Chislehurst, Kent, UK).

9 December, **21st Meeting of the Peptide and Protein Group of the Chemical and Biochemical Societies**, London (Group Secretary, The Dyson Perrins Laboratory, South Parks Road, Oxford, UK).

12–14 December, **International Conference on the Monitoring of Hazardous Gases in the Working Environment**, London (The Chemical Society, Burlington House, Piccadilly, London W1, UK).

12–15 December, **Conference on Conservation, Management and Development of Recreational Freshwater Fisheries**, Oxford (Water Research Centre, Medmenham Laboratory, Henley Road, Medmenham, PO Box 16, Marlow, Bucks, UK).

13–14 December, **Symposium on Electrocrystallisation, Nucleation and Phase Formation**, Southampton (Faraday Division, The Chemical Society, Burlington House, Piccadilly, London W1, UK).

14 December, **Ion Sputtering and Depth Profiling in Surface Analysis**, London (Institute of Physics, 47 Belgrave Square, London SW1, UK).

20–21 December, **Symposium of the Nucleotide Group, Chemical and Biochemical Societies, on Nucleoside and Polynucleotide Synthesis and Structure**, Birmingham, UK (Please send addressed envelope (stamped if from UK) to Dr R. T. Walker, Chemistry Department, Birmingham University, PO Box 363, Birmingham, UK).

20–22 December, **Cell Motility**, London (M. E. J. Holwill, Department of Physics, Queen Elizabeth College, London W8, UK).

Meetings 1978

3-7 January, **International Astro-nomical Union Colloquium on Proto-stars and Planets**, Tucson (T. Gehrels, Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721).

4-5 January, **Fishfarming and Wastes**, London (Society of Chemical Industry, Water and Environment Group, 135 New London Road, Chelmsford, UK).
4-6 January, **15th Annual Solid State Physics Conference**, Coventry (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).

24 January, **Acute and Chronic Effects of Radiation on Man**, London (Professor J. H. Martin, Department of Medical Biophysics, Blackness Laboratory, University of Dundee, Dundee, UK).

25-27 January, **Conference on Muscular Dystrophy and Other Inherited Diseases of Skeletal Muscle in Animals**, New York (Conference Department, The New York Academy of Sciences, 2 East 63rd Street, New York, NY 10021).

26 January, **Symposium on Internal Corrosion of Water Systems**, London (Department of Industry, Committee on Corrosion Secretariat, Room 540, Abell House, John Islip Street, London SW1, UK).

23-26 February, **Asian Congress of Parasitology**, Bombay (D. M. Renapurkar, Secretary General, Asian Congress of Parasitology, Haffkine Institute, Bombay, India).

27 February-3 March, **29th Annual Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy**, Cleveland (United States Steel Corporation Research Laboratory, MS 57, Monroeville, Pennsylvania 15146).

6-10 March, **International Colloquium on Earth Observation from Space and Management of Planetary Resources**, Toulouse, France (Secretariat du colloque, OST, BP No. 4130, 31030 Toulouse Cedex, France).

9-11 March, **International Symposium on Quantum Biology and Quantum Pharmacology**, Palm Coast, Florida (Director, Sanibel Symposia, Williamson Hall, University of Florida, Gainesville, Florida 32611).

29 March-1 April, **3rd International Conference on Submillimetre Waves and their Applications**, Guildford (Institute of Physics, 47 Belgrave Square, London SW1, UK).

2-6 April, **2nd Argentine Congress of Palaeontology and Biostratigraphy and the 1st Latinoamerican Congress of Palaeontology**, Buenos Aires (II Congreso Argentino de Paleontología y Biostratigrafía y I Congreso Latino-

americano de Paleontología, Maipú 645, Primer Piso, 1006-Buenos Aires, Republica Argentina).

10-12 April, **International Conference on Geological Information**, London (International Conference on Geological Information, c/o Palaeontology Library, British Museum (Natural History), Cromwell Road, London SW7, UK) (for those resident in N and S America: D. C. Ward, University Libraries, University of Colorado at Boulder, Boulder, Colorado 80309).

10-12 April, **Symposium on Microprocessors in Analytical Instrumentation**, London (Gerda Holt, Scientific Symposia Ltd, 42-43 Gerrard Street, London W1, UK).

10-13 April, **Utilisation of Sewage Sludge on Land**, Oxford (The Conference Organiser, Water Research Centre, Medmenham Laboratory, Henley Road, Medmenham, PO Box 16, Marlow, Bucks, UK).

11-12 April, **Symposium on the Use of Alternatives in the Discovery, Development and Testing of Therapeutic Products**, London (Symposium Organiser, FRAME, 312a Worple Road, Wimbledon, London SW20, UK).

11-13 April, **Colloid Stability**, Lunteren, The Netherlands (Faraday Division, The Chemical Society, Burlington House, London W1, UK).

nature

27 October 1977

How much further can the pendulum swing?

IN THE past few years the tide of inflation has run so steadily in Britain, and the economy has been so sluggish, that we have rather lost sight of former landmarks and tended to measure performance mainly on the outcome of individual battles and on our ability to survive from year to year. Viewed in a longer time perspective, however, how has science fared in these years? In the Third Leverhulme Lecture in Liverpool last week, the biochemist Hans Kornberg pulled together a number of scattered statistics to show that although we may have survived the battles in some way or another, we are still in danger of losing the war. These matters are of particular interest now that North Sea oil is bringing some relief to a beleaguered economy and everyone who has been asked to make sacrifices is wondering when the sacrificing is going to stop.

Most striking of Kornberg's examples is the way in which expenditure on civil research and development in five European countries moved in the years 1969-74. West Germany, France and the United Kingdom spent respectively 1.5, 1.2 and 0.9 billion (10⁹) Eurodollars in 1969; by 1974 Germany was up to 3.6 billion, France to 2.0 billion . . . and the UK almost static at 1.0 billion. Expenditures in the Netherlands and Belgium, previously down at the 0.2-0.3 billion level, are steadily rising.

The figures do, of course, need extensive qualification. No one who has travelled on the Continent will be unaware of the discrepancies in cost of living which exchange rates seem poorly to reflect. And there are complications between countries in the allowance that is made for social security payments. So a better measure might well be how many people are employed in research and development per thousand of population in each country. But the general shape of the conclusion would be the same: that in Europe, Britain is lagging very seriously in its investment in civil R&D, though still spending heavily in the defence field in its urge to keep in touch with the United States.

Even within the term 'civil R&D', however, there needs to be some attention to detail. In recent years

the Rothschild reorganisation of government R&D and the more recent enthusiasm for engineering has ensured a moderate degree of health for the applied side of things. But with a static total budget this has inevitably meant harder times for the more basic side. In many ways the approach to these harder times has been too subtle to cause individual comment. One such way is the upwards creep of costs, necessary just to stand still. As staff become more senior, they are entitled to higher wages; as research proceeds, more complicated equipment is generally needed. Such costs outstrip cost-of-living scales normally used to adjust authorisations from year to year. As Kornberg puts it, "The pendulum has now swung too far [from the more affluent days of the 1960s] and its action must be reversed if it is not to cause possibly irreversible damage".

Few scientists would need to be reminded of one perfectly valid argument for supporting basic research—that you can never tell what it will turn up, and the occasional discovery, be it Newton's Laws or Mendel's peas or whatever, is infinitely more valuable in the long run than any amount of basic research. But there are two more arguments which should be deployed more frequently. They are, first, that support of basic research is support of a cultural activity, which government ought to have a genuine pride in fostering; and, second, that basic research and indeed basic researchers recognise no national frontiers, and so if support wanes in one country whilst waxing elsewhere British researchers will first have to depend more and more on the kindness of their foreign colleagues and ultimately will move themselves, or recommend their students to move to more fertile pastures.

The erosion is slow and there is no psychologically 'right' time at which to start protesting; besides, scientists recognise as well as anyone that there have been some genuine national needs for economy. But maybe Kornberg's speech, together with the Secretary of State for Education and Science's call a few months ago for a science lobby, will start something. □

The Nobel prizes (1): Physics

Rewarding solid state

Sam Edwards on Nevill Mott,
Philip Anderson and John van Vleck

IT is a pleasure to contribute a note on these awards, as I have had two of the recipients, Nevill Mott and Phil Anderson, as colleagues and have worked with them, and have attended the inspiring lectures of the third, John van Vleck, when a graduate student at Harvard.

Nevill Mott started research in physics when quantum mechanics was recently invented. His first great contribution was to show that quantum mechanics affected the most basic of scattering experiments, that of α -particle-helium collisions. Mott relates that, starting his first research appointment, he went to explain to Rutherford that his famous scattering formula needed amendment and that Chadwick, who came along, had found it was so. Rutherford listened with interest but without comment until Mott rose to leave, when the great man called after him, "If you think of anything else like this, please come and tell me".

This interest of Mott extended to atomic collisions and led to the collaboration with Sir Harrie Massey in their famous text on collision theory; it extended into nuclear scattering and very notably into the theory of internal conversion of gamma rays. His interests in the 1930s, after a move to Bristol, turned to the solid state, and there were many notable contributions to the theory of semiconductors, for example, to the understanding of rectification. This latter problem led him naturally to the study of oxides where he realised that the quantum theory of metals, semiconductors, and insulators, as developed by physicists in the 1930s, seemed quite inadequate to explain why under certain conditions oxides were conductors, whilst in other conditions they were insulators. People with a chemistry background found these facts explainable on structural grounds, but the basic interpretation of the solid state by quantum theory had now reached a level that anything other than a complete *ab initio* explanation of behaviour was inadequate.

It should be remarked that Mott had left Cambridge first for Manchester and then for Bristol where he played a major part in establishing the great eminence of the Bristol physics department, and made great contributions to the theory of dislocations, the theory of fracture and other aspects of the structure of solids, which has long

been a speciality of Bristol, and also to the theory of ionic crystals, a key to the photographic process which led to the famous book written with Gurney. He also wrote another famous book on metals in collaboration with Professor Jones, recently retired from Imperial College. But to return to the events which led to the Nobel Prize, Mott realised that external circumstances could lead a solid to make transitions between metal and insulator configurations, and the Mott transition was born. This study explained in a much deeper way than ever before why a material took up the metallic or non-metallic condition in the crystalline state, and is developed in detail in his book *Metal-Insulator Transitions*.

Back in Cambridge, he realised similar problems must exist in the amorphous state, which also shows metallic, insulator and semiconductor behaviour, and does so in a way which contradicts any straightforward approach. About this time Anderson published his paper 'Absence of diffusion in certain random lattices', which gave a rigorous basis to the phenomena of the localisation of electron wave functions by disorder. A lifetime of experience enabled Mott to see what the physical consequences of localisation would be, and a torrent of new physics resulted. Again this work formed the basis of a major book in collaboration with Dr E. A. Davis who has been Sir Nevill's experimental collaborator. Dr Davis tells me that no sooner does he prepare a new edition of the book than the number of papers in the literature justifies starting again. The phenomena flaring from the new theory include semiconductor switches and the prospect of much cheaper materials for, say, the conversion of sunlight to electricity, a field where Professor Spear has been quick to grasp the significance of the revolution and produce remarkable new amorphous materials.

The stature of Mott's work from the very beginning has been of the highest calibre, but it is perhaps most remarkable that the Nobel citation particularly referred to work done in his sixties, when most people are coasting to rest.

Anderson on magnetism

Phil Anderson started his research career studying aspects of magnetism with Van Vleck at Harvard, and early in his published papers is a notable study of the antiferromagnetic state, where he shows how quantum mechanics introduces great complexity into a problem which is classically so simple. His many early papers on magnetism led him to great facility with the application of quantum mechanical ideas in particular with spin systems into which he always tries to translate problems, since this way of thinking demands a quantal rather than classical intuition. It was natural therefore for him to think of the

Van Vleck, Anderson, Mott

diffusion of spins when he studied the problem of disorder in quantum mechanics in his famous 1958 paper referred to above. The same framework of thought produced impressive contributions to the theory of superconductivity which had been opened up around that time by the BCS theory.

When Anderson took a joint appointment in Cambridge and at Bell Telephones, one of the great fruits of his time in Cambridge was his interaction with Sir Brian Pippard and with Brian Josephson, when Josephson was developing new ideas on superconducting tunnelling which led to his Nobel prize. The other big interaction in Cambridge was with Mott and many other British physicists which has produced many new ideas both in Cambridge and elsewhere in Britain, notably with Professor Thouless in Birmingham.

Anderson also did basic work on helium 3 over this period, and even the application of solid state ideas to astrophysics, but it is his work on the electronic structure of disordered systems and on magnetism which has earned him the Nobel prize. Other notable work on glasses has been on the low temperature thermal properties, and on disordered magnets, the 'spin glasses' where it has been my privilege to collaborate with him.

I have noted Anderson's early and continued interest in magnetism and how it has influenced his other interests. That interest was kindled by J. H. Van Vleck, who brought

magnetism into the realm of quantum mechanics. It is astonishing to realise the rate of progress in understanding in the late 1920s and early 1930s when, compared to today, a small number of scientists revolutionised physics. Van Vleck published the first edition of his *Theory of Electric and Magnetic Susceptibilities* in 1932 and with this virtually the whole of the modern theory of magnetism was set up: not just solved because there are still deep and difficult problems remaining, but just how the classical theory could be absorbed into quantum theory, what the interactions had to be, how the Schrödinger equation was to be studied when crystal fields are present—it is all there, written out in a completeness and clarity which quite belie the date.

Subsequently Van Vleck developed and clarified many aspects of the electromagnetic nature of crystals, whilst also making major contributions to microwave and resonance spectroscopy, fields which have taken on new importance with the discovery of cosmic hydroxyl maser effects, and microwave communications. His work also extended to clarification of the nature of the chemical bond unifying the different valence bond and orbital pictures, but most importantly to the unification of the different models of magnetism. His Nobel award is something which his many advisers have been expecting for some years and gives just recognition for his achievement. □

The Nobel prizes (2): Chemistry

Thermodynamicist

J. S. Rowlinson on Ilya Prigogine

THE Swedish Academy of Sciences has awarded this year's Nobel prize for chemistry to Professor Ilya Prigogine of the Université Libre of Brussels. He was born in Moscow sixty years ago but went to Belgium at an early age, and has spent his whole career there, although for the past ten years he has also held an appointment at the Center for Statistical Mechanics and Thermodynamics at the University of Texas.

Brussels has had a long tradition of research in classical or equilibrium thermodynamics, and although Prigogine has contributed to this field he has done his most important work in two other branches, statistical thermodynamics, which is based on molecular descriptions, and non-equilibrium thermodynamics. He started in the first with some war-time papers which developed the cell theories of liquid structure put forward in the 1930s by Lennard-Jones, and developed them to cover liquid mixtures also. Such theories suppose that a molecule spends most of its time in one of a lattice of cells to which it is confined by its neighbours. To be applicable to liquid mixtures such theories require that each species can be accommodated equally well in each cell.

This work, and parallel work in England and America in the 1950s, was a real advance, but was restricted in its useful application to mixtures of molecules of the same size. His book *Molecular Theory of Solutions* (1957) was influential in its day but is not much used now. The theory of liquids has developed along other lines which eschew the restrictive concepts of lattices or cells.

Meanwhile Prigogine was putting more of his effort into non-equilibrium thermodynamics, a subject which has had a long but not always very productive history. It started in the last century with the study of apparently simple transport processes such as the flow of electric current caused by a temperature difference between two junctions of different metals (Seebeck effect), or the inverse, the evolu-

tion of heat produced by an electric current across a metallic junction (Peltier effect).

Similar coupled flows of matter and energy occur when two fluids mix by diffusion, or when chemical reactions occur in inhomogeneous systems. Kelvin put forward quasi-thermodynamic explanations of some of these phenomena but it was not until 1931 that Onsager brought order to the whole subject by describing exactly how such forces and flows are coupled—his famous 'reciprocal relations' for which he was awarded the Nobel Prize for Chemistry in 1968. An interesting consequence of Onsager's work was Prigogine's discovery in 1945 that such systems are characterised by minima in the rates of entropy production.

These results are, however, limited to systems which are very close to equilibrium so that the flows are always proportional to the gradients of potential which generate them, such as temperature, or electric or chemical potential. They are, therefore, restricted in their applications, particularly if the systems are chemically reactive. One critic of this stage of development of the subject, believing that the useful results were not commensurate with the effort expended, said in 1966 that we should "ask not what we can do for irreversible thermodynamics; ask what irreversible thermodynamics can do for us". It was from this impasse that Prigogine sought to escape.

Within the regime of linear laws he undertook the development of molecular or statistical theories of non-equilibrium thermodynamics. Until the 1950s such theories had been confined to dilute gases and had reached their climax with the work of S. Chapman and D. Enskog during the First World War. The methods they used, however, and even the name of the subject—the kinetic theory of gases—had little in common with equilibrium

Prigogine

statistical thermodynamics. Prigogine, Résibois, and others of the Brussels school have played a leading part in developing kinetic theories that are applicable to all fluids. One of the principal tools of this research has been to exploit the analogies between the Liouville equation, which describes how a molecular system evolves, and the time-dependent Schrödinger equation of quantum mechanics.

A second line of attack has been to push the macroscopic treatment of Onsager beyond the narrow range of situations in which flows depend linearly on forces. If this could be done then a whole range of new phenomena would come within the scope of non-equilibrium thermodynamics, such as the turbulent flow and convective instabilities of hydrodynamics, and chemically reactive systems that oscillate in space or time. However a macroscopic description implies that we can define such statistical properties as pressure, temperature and entropy even if the system is far from equilibrium. Prigogine showed that such an assumption is a sufficient condition for the use of thermodynamic methods and justified it in certain cases, for example, by showing that even in fast gas reactions the molecular distribution of velocities shows little departure from a local Maxwellian distribution.

The behaviour of fluctuations of these local properties distinguishes stable from unstable systems. Spontaneous fluctuations are always occurring but, except at a critical point, are usually unimportant. In a system with weak potential gradients each fluctuation quickly regresses to the steady-state behaviour, but when gradients are large then the fluctuations can grow until a new pattern of flow is established, for example the Bénard cells of rotating elements of fluid in a liquid heated strongly from below. Prigogine has sought to marry the classical theories of

stability of structures with a generalised thermodynamics which would encompass such dissipative systems. He does this by introducing a 'local potential', which is a generalisation of the more familiar chemical potential, and then by using a variational principle to calculate the flows. The boundary between the stable or steady states and the dissipative structures is described by an 'excess entropy production' which is positive for the former and negative for the latter.

These new methods encompass many of the traditional ones used in discussing hydrodynamic instabilities, but their more interesting applications lie in the field of chemical reactions. This is, first, because reaction rates are, in practice, never linear in differences of chemical potential, and secondly because of the biological occurrence of systems in which complex chemical reactions are coupled to flows of matter and energy. He and his colleague, G. Nicolis, have used these methods to investigate the conditions under which reaction systems can oscillate in space and time with the aim of developing a thermodynamics that is applicable to biochemical systems.

Whatever new results emerge it is clear that Prigogine, both by his writings and by his enthusiastic advocacy, has changed the ways in which we can discuss a variety of difficult problems. He is, above all, a man of original ideas. In his book (with P. Glansdorff) *Thermodynamic Theory of Structure, Stability and Fluctuations* (1971), he quotes Bergson's saying of 1907 that the second law of thermodynamics is the most metaphysical of all laws of nature. He adds, "Whether a compliment or a criticism, this applies also to the 'generalised thermodynamics' we develop in this monograph". □

The Nobel prizes (3): Physiology and Medicine

Starting a revolution

Jesse Roth and J. E. Rall on Rosalyn Yalow

DR Rosalyn Yalow was awarded a Nobel prize for medicine and physiology in 1977 for the development of the radioimmunoassay. The introduction of the radioimmunoassay for plasma insulin in humans (R. S. Yalow and S. A. Berson, *Nature* **184**, 1648; 1959; *J. Clin. Invest.* **39**, 1157; 1960) started a revolution in endocrinology which spread from insulin to other peptide hormones including substances previously thought not to be antigenic, to steroid and thyroid hormones and to the cyclic nucleotides. Like other great revolutions it spread rapidly to encompass other fields including clinical pharmacology, enzymology, oncology, virology, immunology and haematology. The recent explosion of studies of cellular receptors for hormones, neurotransmitters, lipoproteins and drugs has its technical and intellectual roots in the radioimmunoassay.

Missing from the Nobel citation is the name of Dr Solomon A. Berson who died in 1972. Nobel prizes are not awarded posthumously, but historians and scientists everywhere recall the hundreds of joint publications of Yalow and Berson in the two decades that flank the publication of the seminal papers that introduced the radioimmunoassay.

To appreciate the revolution that the radioimmunoassay wrought it is necessary to recall the incredible state of endocrinology in 1960. The peptide hormones, which constitute about 80% of all hormones, could not, with rare exception, be measured in blood or other biological fluids. If one wished to study the dynamics of insulin *in vivo*, one could only guess from measurements of the blood glucose, or

some other very distant component in the complex of reactions that regulate the blood glucose. Biological assays were available to measure the high concentrations of hormones in extracts of glands but these assays were orders of magnitude too insensitive and lacked the necessary specificity for measurements of hormones in blood.

How was it possible to measure peptide hormones at concentrations of 10^{-10} M in a sea of contaminating proteins at 10^{-3} M, when these hormones were virtually indistinguishable from thousands of other peptides and proteins in the blood? To solve this problem Berson and Yalow used antibodies to insulin, which they had recently characterised and had shown were capable of binding insulin but no other substances. Insulin that they labelled with radioactive iodine was reacted with antibody that had the desired specificity and the then unheard of affinity constant 10^{10} L/M. Conditions were set so that minute concentrations of unlabelled insulin competed with the labelled insulin for binding to the antibody. By measuring the ratio of radioactively-labelled insulin that was bound to antibodies to that which was free, the precise concentration of unlabelled insulin in the system could be determined.

This simple method of measurement of hormones in the blood was made possible by a series of conceptual leaps and technical innovations by Yalow and Berson in the preceding five years. They discovered that all insulin-treated patients generated antibodies to the hormone and recognised the problem of species specificity among insulins. They recognised the need to find antibodies with affinities so high as to be undreamed of by immunochemists of those days. They introduced methods to protect and purify proteins that were being labelled at high specific radioactivity. They devised a rapid precise method for separating antibody-bound hormone from free hormone and characterised in detail the kinetics and thermodynamics of insulin antibody interaction.

With precise and specific measurements for plasma hormone, it became clear that many of the earlier guesses were incorrect. For example, the radioimmunoassay proved that only a minority of diabetics have an absolute deficiency of insulin. Most diabetics have normal or supernormal amounts of insulin which is biologically intact but the cells of these diabetics are subnormally responsive to insulin. Yalow and Berson not only introduced the radioimmunoassay for insulin but applied the method to study the physiology of many other peptide hormones, including growth hormone, parathyroid hormone, adrenocorticotropin and gastrin. They also used this approach to devise a very sensitive method for detecting hepatitis virus and its antibodies in blood, which is widely used in blood banks in the United States and elsewhere. Other applications to problems of infectious diseases are now emerging. Although just beginning, the extension of radioimmunoassay to measure blood levels of drugs, including cardiac glycosides, anticonvulsants and antibiotics, has made it much more feasible for physicians to achieve therapeutic effects without sustaining serious untoward effects of these agents. The principle of competitive binding assays has been extended beyond antibodies to other binding substances of appropriate specificity and affinity.

In the light of these extraordinary scientific accomplishments, it is interesting to recall Dr Yalow's own modest personal and academic background. Born in 1921, she was raised in the South Bronx, the area that is now recognised as the most devastated in the urban United States. She was the first physics major at Hunter College, and although she graduated *magna cum laude* and *phi beta kappa*, her future was clouded by the fact that she was both Jewish and female, two traits which were not considered to favour success in physics in those days. In part because the military draft was depleting the ranks of eligible males, Dr Yalow was accepted by the University of Illinois, and after receiving her Ph.D in physics she returned to New York, where she worked until the end of the Second World War. In 1947, when applications of radioactive isotopes to clinical medicine were in their infancy, Dr Yalow joined the newly formed radioisotope unit of the

Veterans Administration Hospital in the Bronx where she has worked ever since.

Dr Berson, from a similar background, joined the radioisotope unit in 1950. His participation in the research was much less direct after 1968 when he assumed the chairmanship of the Department of Medicine of the Mount Sinai School of Medicine. In spite of his sudden death four years later, there has continued a flood of exciting new studies from the laboratory (renamed the Solomon A. Berson Research Laboratory) at the Bronx Veterans Administration Hospital under Dr Yalow's

Yalow

solo leadership. It has become clear that each peptide hormone in the blood is not a single substance but is rather a family of related peptides that include the active hormone, modifications of the active hormone, precursors and degradation products, as well as phylogenetically related peptides. Dr Yalow has been the major contributor to this area over the last decade and has extended these observations to numerous biological problems *in vivo*.

Her achievements are the subject of editorials in *The Daily News* and *The New York Post* as well as the subject of hundreds of sermons in churches and synagogues throughout the area. Dr Yalow is being viewed as an example of how talented and determined people of modest background can become world champions even in today's America. Women's groups all over North America have turned to her as a symbol. The Urban Crisis Task Force, which has its headquarters in the South Bronx, sees her as an ideal and has decided to name one of their new housing projects in her honour. □

Inadvertent collaboration

George Fink on Roger Guillemin and Andrew Schally

DR Roger Guillemin of the Salk Institute and Dr Andrew Victor Schally of the Veterans Administration Hospital, New Orleans, were awarded the Nobel prize in physiology and medicine for isolating, characterising and synthesising three polypeptides which mediate the neural control of the anterior pituitary gland. The discoveries of Schally and Guillemin have already proved significant for clinical and basic medical science and are likely to offer new and safer methods for the control of population size.

The delight of neuroendocrinologists will only be dampened by the fact that the untimely death in November 1971 of Geoffrey Wingfield Harris, FRS, prevented him from sharing the fruits of his labours. As a medical student at Cambridge, Harris was the first (1937) to provide experimental proof for the then tentative view that the anterior pituitary gland was controlled by the central nervous system. The elegant studies carried out by Harris in the 1940s and early 1950s, alone and in collaboration with Dora Jacobsohn and the late John Green, established beyond doubt that this control was mediated by a neurohumoral mechanism involving the transport by hypophysial portal

vessel blood of chemical substances from the hypothalamus to the anterior pituitary.

The three polypeptides and their aminoacid sequences are: thyrotrophin releasing factor (TRF) pyro Glu-His-Pro-NH₂; gonadotrophin releasing factor (GnRF) pyro Gly-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH₂; and somatostatin (or somatotrophin release inhibiting factor, SRIF) H-Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys-OH. Synthetic TRF and GnRF are now widely used in the investigation of thyroid dysfunction and infertility, respectively. Because TRF releases prolactin as well as thyrotrophin, the tripeptide is also used for investigating patients in whom prolactin secretion appears to be abnormal. Conceivably, antagonists of TRF may prove useful for controlling hyperprolactinaemia, a condition frequently associated with infertility in women, and for the control of hormone dependent tumours of the breast.

Superactive analogues of GnRF, made by substituting a D-aminoacid (for example D-Trp, D-Ala or D-Leu) for Gly⁶ and an ethylamide group for Gly¹⁰, are being investigated mainly by Schally's group with a view to improving the precision of ovulation in women who prefer to or must use the rhythm method of fertility control. The parent decapeptide has already been used successfully for the treatment of certain types of infertility in men and women. Because GnRF will only discharge the amount of luteinising hormone (LH, the hormone which triggers ovulation) normally available for release, the risk in terms of pro-

ducing multiple pregnancy is negligible compared with that of administering exogenous gonadotrophins. Concern about the safety of the steroid contraceptive 'pill' has added impetus to the search for other chemical contraceptives.

As well as inhibiting the release of growth hormone, somatostatin inhibits the release of thyrotrophin, prolactin, insulin, glucagon and gastrin. In spite of these widespread effects, early trials suggested that the tetradecapeptide may prove useful for the control of certain aspects of diabetes mellitus. An inhibitory effect of somatostatin on platelet aggregation has, however, made it mandatory for clinicians to proceed with caution.

As expected, access to large amounts of the three peptides, which are relatively easily synthesised, has proved invaluable for investigating the physiology and biochemistry of the hypothalamic-pituitary system. Perhaps of greater importance, however, is the fact that the peptides have reawakened interest in extra-hypothalamic peptidergic neurons, a field which has largely remained dormant since the studies of Gaddum and Von Euler on substance P (1931). Using antisera to TRF, GnRF and somatostatin, immunoassay and immunohistochemical studies have shown that relatively large amounts of these peptides are present in areas outside the hypothalamus, including the cerebral cortex and spinal cord.

The small amount of polypeptide in the hypothalamus (nanogram quantities), the protected N and C terminals of TRF and GnRF, and the fact that the hypothalamus contains more pharmacologically active substances than any other tissue, made the isolation of the three peptides exceedingly difficult. Both Schally with Murray Saffran at McGill, and Guillemin in Houston, started their isolation studies on corticotrophin releasing factor (CRF). Subsequently, at Baylor University, they collaborated on this project, but, by the early 1960s, they realised that for various technical reasons, notably the lack of a specific assay for CRF, it would have been better to leave the investigation of this potentially important factor until last.

After Schally became chief of the Veterans Administration Endocrine and Polypeptide Laboratory in New Orleans (1963), the alarming rivalry which soon developed between the two Laureates provided the necessary stimulus for the completion of their Herculean task. Almost every result obtained by one was checked by the other, and, although separated more by passion than distance, much of the work proved inadvertently to be collaborative. Thus, for example, Guillemin and his co-workers were the first to show that hypothalamic extracts could release thyrotrophin (*C.R. Acad. Sci. Paris* **255**, 1018, 1962). Schally's group revealed that His, Glu and Pro were the aminoacids present in porcine TRF (*Biochem. Biophys. Res. Commun.* **25**, 165, 1966). On the basis of the activity of various synthetic tripeptide isomers of these acids, both groups reached the conclusion in 1969 that TRF was likely to be pyro Glu-His-Pro-NH₂.

Shortly afterwards, Guillemin reported that the structure of natural ovine TRF was identical to that of the active isomer as assessed by infrared, mass and nuclear-magnetic resonance spectrometry (*C.R. Acad. Sci. Paris* **269**, 226, 1969; *Nature* **226**, 321, 1970). Schally found that natural porcine TRF was also identical to pyro Glu-His-Pro-NH₂ as assessed by identical Rf values in various chromatographic systems (*Biochem. Biophys. Res. Commun.* **37**, 705, 1969) and by spectral analysis (*Biochemistry* **9**, 1103, 1970).

Samuel (Don) McCann in 1960 and Geoffrey Harris in 1961, using respectively the ovarian ascorbic acid depletion method of Albert Parlow (an assay used extensively by Guillemin and Schally) and the rabbit ovulation test, reported that hypothalamic extracts released LH. After ten years of intense work carried out by several groups, Schally was able to announce in 1971 that his team had determined

the structure of porcine GnRF (*Biochem. Biophys. Res. Commun.* **43**, 393 and 1334). The amino-acid sequence was confirmed by Guillemin's group who used ovine tissues (*Proc. Natn. Acad. Sci.* **69**, 278, 1972). Both groups agreed that the decapeptide releases LH and follicle-stimulating hormone (FSH) (hence Schally's preferred term, LH-RH/FSH-RH). Earlier evidence for the existence of a separate releasing factor for FSH appeared to be due to the non-specific effects of polyamine contaminants. So far there is no convincing biochemical evidence for the existence of a FSH-RF distinct from the decapeptide, and this is disappointing since it makes remote the possibility of developing an acceptable male contraceptive 'pill'.

McCann and his co-workers (*Endocrinology* **83**, 783, 1968) first demonstrated the presence in fractions of sheep and rat hypothalamic extract of a growth hormone inhibitory factor and a growth hormone releasing factor. The structure of ovine growth hormone inhibitory factor (somatostatin) was reported by Guillemin's group in 1973 (*Science* **179**, 77). In spite of extensive studies the structure of growth hormone releasing factor remains unpublished.

Since the isolation of the three polypeptides, Schally's team have focused attention on the development of potent agonists and antagonists of GnRF, as well as on the isolation of prolactin-inhibitory, corticotrophin-releasing and growth-hormone-releasing factor. As well as developing analogues of the peptides, Guillemin has concentrated his efforts on the endorphins, his most significant recent contribution being the isolation of a pituitary protein (MW 31000) which appears to be a common precursor of β -endorphin and ACTH.

Apart from their expertise in chemistry and physiology, and their tenacity and perseverance, the success of the two Laureates depended on the recognition in the early sixties that the isolation of each hypothalamic factor required an all or none approach. They had the capacity to attract research funds amounting to many millions of dollars which enabled them to assemble large teams of competent chemists and biologists, and as well, purchase the many hundreds of thousands of hypothalamic fragments necessary for successful isolation.

Since the late 1950s, when he began to test ovine hypothalamic fragments for LH-releasing activity, Geoffrey Harris was determined to isolate LH-RF. He managed to secure only one senior chemist at a time: first Peter Fawcett at Mill Hill and then (1966) Harry Gregory at ICI. In the light of the resources available to the American teams, it is perhaps remarkable that, using only a few thousand fragments, Gregory had by 1970 isolated six of the aminoacids in GnRF and had shown that this factor had no free α amino groups (*Control of gonadal secretion*, eds. Baird and Strong, page 15). Is there a lesson here for the funding of British biomedical research?

Guillemin, Schally

JET

Permission to land

The delays experienced by the EEC's Joint European Torus (JET) fusion project are over. Chris Sherwell reports

A FULL two years after the matter came before it, the EEC Council of Research Ministers has agreed on the research laboratories at Culham near Oxford as the location for the next stage of the Community's fusion project, JET. The choice, made at a Council meeting on Tuesday, ends a controversial wrangle that has damaged the Community as well as the project. The decision also paves the way for the establishment of a JET Council, the release of funds to boost a stalling research effort and the appointment of a project head.

Political rather than scientific disputes have persistently hamstrung the £100-million project. Contracts for the team based at Culham have had to be extended at the last moment many times, and continuing uncertainties have driven some members away. Only last week Paul Rebut, the present project leader and a strong candidate to head the next phase, warned that rebuilding the team would take at least six months. Over the past 18 months JET has come up at five Research Ministers' meetings, two Foreign Ministers' meetings and one heads of government meeting; there have been six elections, and seven research ministers have changed; so have six foreign ministers and four heads of government.

The site of the project has sparked most controversy. National interest arguments prevented agreement on any of the four sites originally pro-

posed (Ispra in Italy, Cadarache in France, Garching in Germany and Culham in Britain), even when they were eventually whittled down to Garching and Culham. A widely expected decision failed to materialise at a Research Council meeting in March this year, and EEC heads of government passed the matter three months later to the Foreign Ministers. When they too failed to agree, everything seemed to hang on Anglo-German exchanges. But the Schleyer kidnapping intervened, no exchanges took place and JET was not discussed at a Foreign Ministers' meeting in September.

The breakthrough finally came last week when the West German Chancellor, Helmut Schmidt, and the UK Prime Minister, James Callaghan, met in the aftermath of the successful Mogadishu raid. Its euphoric effects, and Britain's supporting role in it, may have helped the two men submerge differences on matters like Community budget contributions. They agreed that a site for JET should be decided by a consensus—in other words, that neither country would veto whatever preference the majority expressed. This was conveyed to the Foreign Ministers' meeting in Luxembourg the same day, and though Germany did not waive her claim for Garching, the immediate presumption, based on past voting intentions, was that JET would go to Culham when the Research Ministers met in Luxembourg. In the event, five countries voted for Culham and two for Garching. One of the two abstaining countries went with the majority. Earlier fears of an Irish veto proved unfounded.

Reports that two JET projects were being discussed gained credence at a press conference in Brussels on Mon-

day given by Guido Brunner, the EEC's Energy and Research Commissioner. Culham and UK Foreign Office spokesmen last week discounted the idea, the former pointing out that even if this referred to the possibility of siting 'Super JET' or 'Jumbo JET' (as the next phase is known) in the country which failed to win JET, such a decision could not be taken bilaterally. The impression nevertheless remained on Monday that the Research Ministers would take a consensus view on locating the next phase at the losing site, and that ancillary fusion research might also be used as compensation.

The removal of other potential obstacles at a meeting of high-level officials a week earlier also assisted agreement on a JET site. Helpful concessions from France, which originally proposed a JET Council to manage the project and saw it become a stumbling block, produced agreement that the member states, along with other participating countries (Sweden and Switzerland), would each have two members on it, one a scientific expert. Voting will be weighted, 26 out of 37 constituting a majority. The Council, which will have a scientific council to consult at its convenience, will meet as and when necessary. Once it is established (initially in interim form) and funds become available, the senior scientific appointment for the project will be made. But that could prove as politically contentious as anything that has befallen JET so far.

The aim behind the £100-million project—often forgotten by the politicians, often simplified as "cheap, safe and abundant energy supplies"—is essentially to construct a third-generation tokamak device. The equivalent device in the USSR is known as T-20, in the USA as TFTR, and in Japan as T-60. □

DIOXIN

Informing on 2,4,5-T

Alastair Hay looks at two recent reports on the controversial herbicide 2,4,5-T

MANUFACTURERS and users of the herbicide 2,4,5-T are not letting attacks on it pass without comment, if two recent reports that attempt to vouch for its safety are anything to go by. The first, a Dow Chemical Company report to the US Environmental Protection Agency (EPA), insists that there is no "significant hazard" to humans asso-

ciated with its use. The second, from the UK Forestry Commission, claims that if foodstuffs or water supplies should become contaminated with 2,4,5-T, "serious consequences [for humans or animals] are unlikely" to occur.

The use of 2,4,5-T has aroused concern since the late 1960s when formulations of the herbicide in use in Vietnam were shown to be contaminated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (dioxin), which is highly toxic and a known teratogen. The public outcry,

together with scientific criticism of the use of 2,4,5-T, led the EPA to prohibit its use around homes, recreational sites, aquatic areas and on human food crops. In 1975 an EPA study reported that dioxin had been found in beef fat taken from cattle in areas where 2,4,5-T was known to have been used.

The Dow study was undertaken to assess these EPA findings. In a two-year study Dow scientists fed rats diets containing 0.1, 0.01 and 0.001 $\mu\text{g kg}^{-1}$ of dioxin a day. The animals receiving the highest dose experienced the known clinical and pathological symptoms of dioxin exposure—decreased weight gain, decreased red blood cell and

haemoglobin levels, elevation of some serum enzymes, and increased mortality. Discernible increases in the incidence of liver cancer and carcinomas of the lung, hard palate and tongue were also observed. But the report also speaks of a remarkable decrease in the "incidences of tumours of the pituitary, uterus, mammary glands, pancreas and adrenal gland" in these animals. In the rats receiving the lower doses of dioxin a lesser degree of toxicity was observed but there was no increase in tumours. On the basis of these results the report states that if the EPA measurements are used then the average person would need to consume fifty times his "body weight in beef every day to receive the daily dose level" of dioxin linked with cancer incidence in Dow's studies. Thus, in Dow's view it appears that 2,4,5-T is safe if used properly.

The same conclusion is drawn by the Forestry Commission report, 'The Safety of Herbicides 2,4-D and 2,4,5-T'. The author, D. J. Turner, describes many of the criticisms of the use of 2,4,5-T as unfounded and ill-informed. He points out that 2,4,5-T, still enjoying widespread use in Europe and South-East Asia, remains the most effective herbicide for defoliating rubber trees, which is the way to contain and isolate the South American

leaf blight disease *Dothidella ulei*. But he also says that "if reaction conditions [for converting tetrachlorobenzene to trichlorophenol—the precursor of 2,4,5-T] are properly regulated dioxins are not formed". Chemists knowledgeable in reaction mechanisms say this is not so, arguing that the reaction makes dioxin contamination unavoidable and that control of the reaction conditions will only limit the amount of dioxin produced, not eliminate it entirely. In their view the manufacturing stage presents greater risks of dioxin contamination than the use of the herbicide in silviculture.

In spite of the now considerable volume of literature relating to dioxin's effects, the report claims there is no evidence that the "defoliation spraying programmes in Vietnam had any direct effects on humans". This is flatly contradicted in the fifteenth report of the International Agency for Research on Cancer (IARC). In a chapter on chlorinated dibenzodioxins that cites the same National Academy of Sciences report referred to in the Forestry Commission publication, this states that the Montagnard people of South Vietnam were badly affected by exposure to the herbicide 'Agent Orange', a 50:50 mixture of the n-butyl esters of 2,4-D and 2,4,5-T,

containing up to 30 mg kg⁻¹ of dioxin. The consequences included diarrhoea, vomiting, skin rashes, fever, abdominal pain and the deaths of some children. The IARC publication, one of the most comprehensive reports yet produced on the dioxins, aimed to assess carcinogenicity of chlorinated dibenzodioxins, but concluded that this evaluation could not be made with the data available to it at the time of publication.

At Séveso in Italy—where the authorities are now satisfied that decontamination following last year's release of dioxin has made it safe for people to return to their homes (last week the first 24 families were allowed back)—135 children have chloracne as a result of dioxin exposure. A total of thirty-three adults but no children have neurological disorders, yet if (as some argue) chloracne is an obligate sign of dioxin poisoning, children might have been expected to have neurological problems. No eye damage has been reported in the 400 people examined by an oculist. Sixteen cases of children born with malformations were reported by August this year, of whom two died, but the diversity in the type of malformation and the fact that the number was no greater than the statistical norm suggests that dioxin was probably not the causative agent.

THE development of a new chelating agent does not usually make headlines in the national press, but this week saw the widely publicised announcement of a chelating agent with two important differences. Its scientific interest lies in the fact that it can enter the cells of the body and will therefore be much more efficient at removing heavy metal contamination. The reason it hit the headlines is that it has been developed (at the Harwell laboratories of the UK National Radiological Protection Board) to remove plutonium from the body in the event of an accident.

One of the problems in devising effective treatments for the rare cases of accidental contamination with plutonium has been the difficulty of removing the plutonium which becomes locked up in the cells of the body, mostly in liver and bone, where over the years there is the risk that it might induce cancers. The only available treatment up to now aimed to inactivate the plutonium when it was freely accessible in the blood before it became deposited inside tissue cells. The chelating agent calcium diethylene - triamine - pentaacetic acid (CaDTPA) can pick up plutonium from the bloodstream and the resulting complex is excreted in the urine.

But CaDTPA has one great drawback—it cannot enter cells and so is only effective against plutonium circulating in the blood. In real life the

Fighting plutonium

Handling plutonium fuel assembly (BNFL)

BACKGROUND

contaminant may well be 'insoluble' plutonium, such as plutonium dioxide particles, which leach very slowly into the bloodstream from the lungs; in this case DTPA is not particularly efficient in reducing the total body burden.

The NRPB's new drug, which it calls Puchel, is a derivative of DTPA

with one important modification. Fatty acid chains have been added to the molecule enabling it to penetrate the lipid cell membrane and pick up plutonium from inside the cell. The complex is then excreted, mostly in the faeces. The NRPB is not yet divulging the structure of its new molecule, pending a possible patent application, but the secret apparently lies in the length of the fatty acid chains.

So far, of course, the drug has only been tried out in animals, where it has proved essentially non-toxic when given as the calcium salt. Injected intraperitoneally into hamsters it released most of the plutonium deposited in the liver after injection of a soluble plutonium salt, and given as an aerosol removed plutonium from the lung after inhalation of plutonium particles. It will also probably be effective in removing intracellular metal if given orally. Puchel has proved less effective at releasing plutonium from bone than from liver.

Puchel has been developed as a contribution towards reducing the risks of a nuclear accident, but if it proves itself it may be useful in cases of poisoning with non-radioactive heavy metals such as lead and mercury.

IN BRIEF

ISEE OK

The first stage of the joint European-American International Sun-Earth Explorer (ISEE) satellite mission was launched successfully at the weekend. Lift-off was postponed from 13 to 19 October and then suffered two further delays. This was to allow NASA to adjust the Thor Delta vehicle, launching the ISEE A and B satellites in tandem. The second part of the mission, ISEE C, will be launched in nine months' time.

Whale decision

A Federal Court of Appeal has rejected the Alaskan Eskimos' plea that the US Administration be required to file an objection against the International Whaling Commission's (IWC) decision

to bar the hunting of bowhead whales next year. The Court upheld the US decision not to object to the ban. It did so on the grounds that a US refusal to abide by IWC recommendations would give other countries licence to follow suit and would seriously threaten the bowhead with extinction, whose numbers are estimated at between 500 and 2,000.

Washington meeting

An idea to curb the spread of nuclear weapons by setting up an International Fuel Bank was suggested by President Carter last week at the opening of the 40-nation international conference on nuclear fuel disposal. The Bank would ensure the US and other countries of an adequate supply of uranium for

peaceful purposes. The US government also has a plan for storing all spent nuclear fuel produced by reactors both at home and abroad, which would further reduce the Administration's fears of unchecked proliferation.

Med meeting

A five-day meeting of 13 Mediterranean states and the EEC to discuss the draft of a treaty to fight Mediterranean pollution, ended this week with agreement on limiting or banning the discharge of certain materials. The United Nations Environment Programme (UNEP) estimates that the cost of implementing the treaty, which will be submitted to Mediterranean states at a major conference next January, at \$5 billion.

CONSERVATIONISTS, anxious to preserve the native animals and plants of the countryside, generally assume that modern agricultural techniques are increasingly damaging to wildlife. The wholesale removal of hedges in the cereal growing areas of eastern England has, locally, left few wild habitats, spray drift from carelessly used weedkillers has denuded roadside verges of many attractive flowers, and some insecticides have slaughtered thousands of songbirds. However, these abuses are being generally controlled today, and in Britain there is growing cooperation between farmers, the makers of agricultural chemicals and conservationists to make at least the second best of both worlds, of agricultural productivity and wildlife conservation.

It is also encouraging to find that some modern farming methods do less damage than those which they are replacing. Ploughing, the traditional means of cultivation, is a drastic process, with profound effects on soil structure and chemistry and on all subterranean living organisms. It is done to produce a tilth for planting, and to control weeds. Work at Rothamsted Experimental Station in England over thirty years ago showed the surface-casting earthworms, which produced Charles Darwin's 'vegetable mould' (the stone-free well-textured surface layer in old pasture), were eliminated, and their populations might not recover for 70 years. Where cereals have been grown continuously for many years using only chemical manures, levels of organic matter have fallen and soil structure has suffered. Ploughing also uses a lot of expensive and scarce fuel.

Some farmers are now ceasing to plough, and are turning to direct drilling. A field of wheat is harvested, and the straw and stubble is burned. This burning, if improperly controlled, can do immense damage to the countryside, to hedges, woods and verges, and their wildlife, and bodies

Drill to till

KENNETH MELLANBY

like the National Farmers' Union are trying to discipline their members to accept a safety code. But burning has many agricultural advantages. It gives some control of diseases, weeds and pests, and returns a substantial amount of immediately-available nutrient to the soil. A burned field, with little trash on the surface, is easily cultivated, and rain does not produce a quagmire as it does after ploughing.

The field is usually left for some

weeks after burning, to allow weeds and shed grain to germinate. During this period it is a rich feeding ground for birds which obtain little food where stubble is ploughed straight after harvest. The surface is next sprayed with the herbicide paraquat, which kills the growth, but which is immediately immobilised. The sprouting grain is unharmed, and thus it is possible to drill the seed at the same time. This saves a lot of fuel. There has in the past been controversy about the effectiveness of direct drilling, as some farmers have obtained higher and some lower yields than with conventional ploughing. It seems now that good results are obtained by those who persist even after initial disappointment. After three or four years, even on heavy clay soils, the organic matter level increases (as several tonnes per hectare of roots rot down to produce humus) and the soil structure improves markedly. The soil fauna, including the delicate worms, also flourishes, and makes its contribution. The amount of herbicide used may be less than on ploughed fields, for some weeds are killed by the paraquat and the rapidly-germinating crop may smother others, including the usually troublesome couch grass.

Direct drilling is done to help the farmer to grow the most profitable crops, not to please the conservationist. It will not bring back our flower-rich meadows or the hedgerows once full of singing birds. But it may make the soil healthier and support a richer soil fauna. This is the basis of healthy agriculture and a healthy countryside. We, the conservationists, must now find how to encourage wildlife in this milieu.

news and views

Gene derepression in tumours

from Robert Shields

MANY non-endocrine tumours produce a wide variety of peptide hormones; perhaps the best known example is ACTH, (adrenocorticotropin) secreted by oat cell carcinoma of the lung (Rees *J. Endocr.* **67**, 143; 1975). The favoured explanation for this ectopic hormone production is that it results from 'gene derepression' which is claimed to be a frequent occurrence in neoplasia (Odell *New Engl. J. Med.* **297**, 609; 1977). This idea goes some way towards explaining many of the features of ectopic hormone synthesis. Quite often these hormones are larger than the normally occurring peptides (as happens with ACTH). These larger proteins are probably the prohormone precursor to the normal mature protein. Other ectopic hormones lack the modifications normally made before secretion; for instance the subunits of human chorionic gonadotropin (hCG) secreted ectopically by a variety of tumours lack the normal complement of carbohydrate. The gene derepression hypothesis could also explain why ectopic insulin production (which requires the tumour to execute the correct cleavage of proinsulin) is seen so rarely and why ectopic synthesis of non-peptide hormones such as steroids or thyroxine (which would involve the derepression of an entire enzyme pathway) has not been found.

But a number of observations are not fully explained by a simple gene derepression hypothesis. First, if gene derepression is common in neoplasia why do cells plump so often for hormones when there are 1×10^4 – 5×10^4 other genes to choose from? A partial answer may be that most of these genes code for housekeeping functions, over-production of these might be lethal. However, one might still expect luxury proteins to be derepressed with roughly equal frequency. Ectopic production of non-hormone proteins is in fact seen quite often, the best known examples are carcinoembryonic antigen (CEA) or α foetal globulin and

placental alkaline phosphatase. It is probable that many other proteins are synthesised ectopically, and that only the lack of clinical symptoms or suitable assays prevents their detection (Odell & Wolfson in *Cancer*, 81, (ed. Becker F.) Plenum, New York, 1975).

In spite of this range of tumour products specific tumours tend to be associated with particular proteins: squamous carcinoma of the bronchus often produces parathyroid hormone (PTH) but seldom makes ACTH or MSH (melanocyte-stimulating hormone) whereas these hormones are relatively common in oat cell carcinoma (*Br. Med. J.* **1**, 1300; 1976). Why 'gene derepression' (if that is the explanation) occurs so non-randomly has not been satisfactorily explained.

The relative frequency of ectopic hormone production makes it worth asking whether ectopic protein production is unique to neoplasia and whether gene derepression is widespread in tumour cells. A recent report presents evidence for the presence of the β subunit of hCG in liver and colon from normal subjects (Yoshimoto *et al. Science* **197**, 575; 1977). Like ectopically synthesised hCG the protein lacked carbohydrate. Other experimenters have reported finding ACTH in non-involved lung tissue from patients with lung cancer (Bloomfield *et al. Clin. Endocr.* **6**, 95; 1977). These results suggest that ectopic hormone production may be widespread and occur in normal tissue as well. These findings also cast some doubt on the usefulness of ectopic hormones as tumour markers.

mRNA changes

As the techniques of nucleic acid hybridisation become more refined it is possible to ask more directly whether gene derepression occurs in tumour cells. If cDNA to total mRNA from transformed cells is cross-hybridised to normal cell mRNA any unhybridised cDNA should represent sequences present only in the transformed cell. If this remaining cDNA

is then back hybridised to transformed mRNA an estimate of the abundance and complexity of the new mRNA species can be obtained. When such experiments were done with human fibroblasts transformed by SV40 virus it was found that the great majority of mRNA species in transformed cells were present in the normal cells as well (Williams *et al. Cell* **11**, 901; 1977). At most around 3% of the mRNA in tumour cells was new (and part of this was probably virus coded) so vast host gene derepression did not occur. The estimate of how many new host cell sequences were derepressed can only be approximate but the authors calculate that around 35 new species may be involved. Since there are around 10^4 different mRNAs in the cell anyway 35 sequences does not represent large amounts of new information.

In these experiments care was taken to maintain normal and transformed cells under identical conditions to minimise the possibility that the differences seen were unconnected with transformation. Real tumours do not bother with these precautions and it might be expected that their mRNA patterns would diverge widely from normal. Surprisingly when mRNAs from HeLa cells was compared with those from normal cells there was very little difference once again suggesting that few new mRNA sequences were present in this abnormal cell. This result is particularly interesting as some clones of HeLa produce ectopic hCG (Lieblich *et al. Nature* **260**, 532; 1976; Ghosh *et al. Biochem. J.* **166**, 265; 1977). Whether hCG was produced in the clone examined by Williams is not known (Williams, personal communication), but in any event the number of new sequences in HeLa cells may be rather small.

These hybridisation experiments are only accurate in detecting entirely new mRNA transcripts. They are relatively insensitive to switching of mRNAs from low to moderate abundance classes. In other words, some mRNAs that are present in only a

few copies in normal cells may be present in tenfold greater amounts in transformed cells (and *vice versa*) and this would not be picked up. Viral transformation is known to affect the levels of mRNA for host proteins such as LETS and collagen (Adams *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 3399; 1977) and it would be surprising if other mRNAs remained unaltered.

Protein changes

Many experiments suggest a close relationship between the amount of mRNA and the amount of protein produced, so one indirect way to detect alterations in the levels of mRNA species is to examine the spectrum of proteins produced by normal and transformed cells by 2-D electrophoresis. There are relatively few differences in freshly transformed cells but when cells have been in culture for some time the differences are remarkable. Examination of the proteins from established lines of 3T3 cells, or 3T3 cells transformed with SV40 (DNA virus) or Kirsten sarcoma virus (RNA virus) revealed that although both transformed cell lines were similar to each other they differed from their untransformed counterparts in that around 30% of the proteins detectable in the transformed cells were not detected in untransformed cells (Strand & August *Proc. natn. Acad. Sci. U.S.A.* **74**, 2729; 1977).

Many of these 'new' proteins may not be new at all but represent increases in protein that were below

the level of detection in untransformed cells. Also some of these 'new' species may result from different patterns of glycosylation and other modifications in transformed cells which would alter the electrophoretic mobility of pre-existing proteins. Still other proteins may be induced because of differences in the utilisation of the culture medium by transformed and untransformed cells (Shill *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 3840; 1977). Nevertheless, the results show that these cells differ widely in the relative amounts of different protein produced and by inference in the relative amounts of many abundant mRNAs. If one can extrapolate from the experience with human cells (Williams *op. cit.*) (where few new abundant mRNAs were detected) it seems likely that the differing patterns of gene expression in normal and transformed cells may be due more to modulation of pre-existing mRNA sequences than introduction of new genes by oncogenic viruses or the derepression of pre-existing genes.

Whether this is generally true or not must await the preparation of cDNA probes to large numbers of different messages so that specific mRNA levels can be monitored directly after transformation and during evolution in cell culture. Perhaps a good way to start would be to prepare probes specific for ectopically produced proteins to see if mRNAs for these proteins are always present in normal cells (as the data of Yoshimoto *et al. op. cit.* might suggest) or whether these genes are really derepressed in tumour cells. □

then being made by comparing the rate of the drops' fall under gravity with the rise when an electric field is superimposed.

Millikan's original work involved studies of droplets of water or alcohol. On page 220 of his article in the *Philosophical Magazine* of February, 1910 he notes 'I have discarded one uncertain and unduplicated observation apparently upon a singly charged drop which gave a value of the charge . . . some 30% lower than the final value of e '.

This observation was remembered by many people recently when possible evidence for fractional charge was reported in the literature (La Rue *et al. op. cit.*). However the probable cause of Millikan's anomalous result is given by him only two paragraphs later in his paper: singly charged drops were so small that they evaporated rapidly during observation, hence a poor value of e was obtained. To avoid this evaporation problem Millikan ' . . . replaced the droplet of water or alcohol by one of oil, mercury or some other non-volatile substance . . . ' (*Phys. Rev.* **32**, 351; 1911). Never again did he see a fractional charge and one can safely conclude that evaporation was indeed the source of his spurious result.

If one intends to mount a search for quarks, whose occurrence as isolated particles sitting in lumps of matter is at best extremely rare, then one will want to study as much material as possible. The Millikan procedure is fine for very small drops where air friction can be used as a gauge for measuring the small forces on a charge in an electrical field. To study drops with masses of order 10^{-6} – 10^{-7} g an alternative technique is required. Hence studies turned to levitation of ferromagnetic or diamagnetic and superconducting materials by applying external fields. As an example of these experiments one can cite Gallinaro and Morpurgo (*Phys. Lett.* **23**, 609; 1966) who find no evidence for fractional charge in an experiment where more than 10^{-6} g of graphite were studied in a magnetic levitation spectrometer.

Possible evidence for fractional charge on a ferromagnetic material appeared in an experiment where twelve steel balls of 0.2 mm diameter were suspended in turn in a magnetic field. An electric field of $3,000 \text{ Vcm}^{-1}$ was then applied and the charge on the ball deduced. Of the 12 balls 10(!) had charges consistent with $\pm 1/3e$ and only one was consistent with integral charge. However, the authors (Garris & Zioc Nucl. Inst. Meth. **117**, 467; 1974) noted a source of systematic error, namely that due to

What price free quarks?

from F. E. Close

ALTHOUGH the concept of quarks as basic constituents of matter is almost universally accepted no evidence for isolated quarks has yet stood the test of time. However, interest in the search for 'free' quarks was heightened recently in the light of reports of new measurements of e , the magnitude of the element of electric charge, using variations of the Millikan oil drop technique (La Rue *et al. Phys. Rev. Lett.* **38**, 1011; 1977; Gallinari *et al. Phys. Rev. Lett.* **38**, 1255; 1977; Bland *et al. Phys. Rev. Lett.* **39**, 369; 1977). Quarks are widely believed to have fractional electric charge ($2/3$ or $-1/3$ of a proton's charge) and if they can exist as free particles then this property would make them easily

recognisable; hence the interest in the above experiments.

Measurements of e

In advance of Millikan, Ehrenhaft and others (refs in Millikan *Phys. Rev.* **32**, 349; 1911) had deduced the magnitude of the elementary charge from the average behaviour of charged particle swarms in electric and gravitational fields. Millikan appears to have been the first person to make a measurement by studying a single charged carrier, and the result quoted in his 1917 paper (*Phil. Mag.* **34** No. 199, July 1917) is within 1% of that accepted today. Every physics student has met the ideas behind this experiment whose essential feature is that extremely small drops of oil ($\approx 10^{-12}$ g) are observed in an electric field; an accurate determination of the charge

crystal structure and impurities metal surfaces are not equipotential surfaces. These 'patch effects' cause the potential of the metal surface to vary by 50 to 100 mV from place to place hence inducing a field gradient which can act on dipole moments induced in the balls by the applied electrical field. Reinserting several of the balls four months later the deduced charges had altered by as much as $0.45e$ showing that there is a long term change in the patch effect. The authors note that time-dependent changes in the patch effect could have caused a spread in the observed charge covering the measured range and so one cannot conclude that this experiment provides positive evidence for fractional charge.

Recent excitement was generated by reports of evidence for fractional charges on superconducting niobium (La Rue *et al. op. cit.*). Eight niobium balls each of mass $\approx 10^{-4}$ g were levitated in turn in a magnetic field. The charge on a ball can be changed at will by β^+ or β^- emitters adding positive or negative units of electronic charge to the ball. By studying the oscillations of a ball in the field the total force on the ball is deduced. The experimental problem which is crucial to interpreting the results is to decide the extent to which dipole forces might mimic a charge. Much of the paper is devoted to discussing these effects. The conclusion is that five niobium balls heated on a niobium substrate had charges compatible with zero whereas three balls heated on a tungsten substrate had charges of $(+0.337 \pm 0.009)e$, $(-0.001 \pm 0.025)e$, $(-0.331 \pm 0.070)e$ which, if genuine charge effects, are remarkably consistent with quark expectations.

If correct, it has been suggested that the earlier failures to find quarks might be understood if isolated quarks had some preference for existing on heavy nuclei. This does not seem to be borne out however as Bland and coworkers (*op. cit.*) have recently suspended tungsten particles in an electric field. A radioactive source can change the charge on a particle and the new electric field that balances the ball against gravity is determined. Sixty-nine balls were studied and no evidence for fractional charge on a ball was found. Over 10^{12} atoms of tungsten have been studied in this experiment and the authors plan to extend their study to other heavy elements.

Another null result has recently been reported by Gallinaro *et al. (op. cit. 1977)*. These authors studied iron balls of masses $\approx 10^{-4}$ g each and find no evidence for isolated quarks in over 10^{21} nucleons.

Ironically the observation of an isolated fractionally charged quark would

now cause more turmoil to theorists than its non-observation even though all are convinced that the quark concept is correct. Much effort is being devoted to see whether quarks can theoretically be confined inside hadrons in groups of three or as quark-antiquark pairs since these are what seem to be the rules in Nature.

A fifth quark, but no quarks

A recent discovery is that of a new particle, the upsilon (see *News and Views* 268, 297; 1977), which provides the first evidence for a possible fifth flavour of quark. The upsilon has

similar metastability to the ψ (*News and Views* 257, 535; 1975) but is approximately three times as massive (the ψ discovery in 1974 provided the first clear evidence for the existence of the fourth flavour—the charmed quark). It seems that the upsilon is a bound state of a new quark and its antiquark in analogy to the ψ being a bound state of a charmed quark and charmed antiquark.

Hence we have now evidence for five types (or flavours) of quark, yet the intensified search for an isolated quark reveals no sign of one. The quark paradox continues to deepen. \square

Rapid RNA sequencing

from Maria Szekeley

1977 has proved a fruitful year for nucleic acid sequencing. After the outstanding results with DNA achieved with new methods which shorten the time required for sequencing from years to weeks, these new principles have now been introduced to the temporarily neglected field of RNA sequence determination.

Several new developments have been reported at the same time. An RNA sequencing method based on the same principles as Maxam and Gilbert's DNA sequencing technique has been worked out simultaneously by Donis-Keller, Maxam and Gilbert (*Nucleic Acids Res.* 4, 2527; 1977) and by Brownlee's group in Cambridge (Simoncsits *et al.* (See this issue of *Nature*, page 833). This is also a rapid gel sequencing technique in which RNA fragments all ending at a given base are fractionated according to size so that the positions of this base in the RNA sequence can be read off the gel electrophoretic pattern. There is some difficulty involved in the production of these fragments from RNA. Splitting by base-specific endonucleases is used in place of the chemical reactions used for DNA. Although specific cleavages at purine residues are easy to achieve (RNase T_1 is specific for G, RNase U_2 for A in appropriate conditions), there are no enzymes available which split only at C or only at U residues. Simoncsits *et al.*, overcome this difficulty by using pancreatic RNase and RNase I from *Physarum polycephalum*. The former cleaves at C and U, the latter at A, G and U. By comparing the patterns obtained from the four enzymic digests it is therefore possible to deduce the positions of all four nucleotides, although with not quite 100% accuracy. The method may be improved; at its present stage the sequences obtained still need some

further confirmation. But it is rapid, sensitive and widely applicable and thus represents a very important new approach in RNA sequencing.

The other highly efficient gel sequencing technique—Sanger's plus and minus method (See *News and Views*, 267, 104; 1977) has also been adapted to RNA by Brownlee and Cartwright (*J. molec. Biol.* 114, 93; 1977) and has been successfully applied to three eukaryotic messengers: ovalbumin, globin and immunoglobulin mRNAs. The principle is the same in DNA and RNA sequencing, but different enzymes are used. cDNA is synthesised on the RNA template by reverse transcriptase and the same enzyme is used in the minus systems to extend these DNA fragments. Degradation of the DNA fragments in the plus systems is achieved by making use of a hitherto unknown property of DNA polymerase I: in the presence of Mn^{2+} ions this enzyme shows a 3'-exonuclease activity towards the DNA strand of a DNA:RNA hybrid.

There are still some difficulties: interference by RNase activity of reverse transcriptase, anomalies in copying regions of the template where long hairpin loops are present. Ambiguities could, however, be corrected and the above anomalies even proved useful in some cases to locate hairpin loops in the RNA. The accuracy of the technique is not always perfect, occasional artefacts may cause minor mistakes, as is the case also with Sanger's technique. The sequences obtained should therefore be confirmed by other sequencing methods. Still, the possibility of working out a 200-residue long sequence in one experiment, to at least 90 to 95% precision is a development which will greatly accelerate studies on RNA structure.

It is predictable that progress

will be fastest in the study of eukaryotic messengers, not only because these molecules are at the centre of interest, but also because Brownlee's method is especially suitable for messenger RNA sequencing. Reverse transcriptase requires a primer to synthesise cDNA. This is perhaps the only drawback of the method, as the synthesis of oligonucleotide primers is time-consuming and presupposes some knowledge of the RNA sequence. But the poly(A) tail of eukaryotic mRNAs facilitates this task: a 10-residue long oligo(dT) or more suitably an oligo(dT) to which two nucleotides, complementary to the 3' terminal dinucleotide of the mRNA, are attached, can anneal to the beginning of the poly(A) tail and enable the reverse transcriptase to start copying the mRNA exactly from the 3' terminus. Brownlee and Cartwright worked out in this way a 172-nucleotide long sequence from the 3' terminus of ovalbumin mRNA. Although they had to use 13 gels to find the best conditions and to correct the ambiguities, the sequence of the major part could be read off a single gel.

The most interesting recent result of the rapid gel sequencing techniques is the completion of the nucleotide sequence of a eukaryotic messenger: rabbit β -globin mRNA. The structure of this RNA species has attracted keen interest since the isolation of the first pure mRNA. The first attempt to determine the nucleotide sequence of globin mRNA was made years ago and since then practically all sequencing techniques have been applied to this RNA at one stage or another to elucidate some part of its structure. Progress was initially rather slow: the classical techniques had only limited application to large molecules which could not be labelled *in vivo*. Copying techniques were introduced; in dif-

ferent laboratories different enzymes were used to produce highly labelled complementary strands to mRNA which could be subjected to fingerprint analysis. In Cambridge, Proudfoot and Brownlee synthesised cDNA from globin mRNA with the aid of DNA polymerase I (*Nature* **252**, 356; 1974; *J. molec. Biol.* **107**, 491; 1976). At Harvard and Yale, Forget *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **72**, 3614; 1975) and Marrotta *et al.*, (*Progr. Nucl. Acid Res. molec. Biol.* **19**, 165; 1976) applied a double transcription procedure, using reverse transcriptase on globin mRNA to obtain a cDNA transcript which in turn was copied into cRNA with *Escherichia coli* RNA polymerase. Salser's group at the University of California followed similar principles, sequencing parts of the cDNA and parts of the cRNA (*Progr. Nucl. Acid Res. molec. Biol.* **19**, 177; 1976). Lockard and RajBhandary at Massachusetts Institute of Technology used the 'wandering spot' procedure to determine the 5'-terminal capped structure (*Cell* **9**, 747; 1976). As a result of these different approaches major parts of the primary structures of rabbit globin and human globin mRNAs have been established.

In the April issue of *Cell* the long-awaited complete sequence of this mRNA has been published. Baralle (*Cell* **10**, 549; 1977) and Proudfoot (page 559) describe the 5' and 3' noncoding regions, respectively, applying the rapid gel sequencing technique of Brownlee and Cartwright. At the same time, Efstratiadis, Kafatos and Maniatis, using the gel sequencing technique of Maxam and Gilbert, determined the nucleotide sequence of their synthetic globin gene and thus also derived indirectly the sequence of globin mRNA (page 571). They present a 576-nucleotide long sequence almost complete in itself. The perfect agreement of this sequence with partial information available on the mRNA structure and

with the amino acid sequence of the protein proves that genes produced by *in vitro* transcription of mRNA and cloning of the double-stranded DNA product are faithful copies. □

Poland's 'fifth problem'

from I. J. Smalley

THE Polish government has defined nine major problems which are to be investigated by the country's scientists and engineers. These include such basic topics as developing a national electronics industry, finding a cure for cancer and tackling the difficult problem of water supply in a country with only one major river system. The fifth problem is housing—trying to find ways of overcoming the shortage of housing units in Poland. Such was the destruction caused in Poland during the Second World War that the housing balance has still not been restored.

Within project 5 perhaps the most urgent need is to find alternative sources of building materials, and this is closely followed by a need to improve the organisation of the building industry. The modern building material is concrete and for general purpose construction there is no real alternative. In a normal concrete only about 25% of the volume is occupied by the cement paste while the remaining 75% is occupied by inert space filling aggregate—and Poland is very short of aggregate.

Various approaches to the building material problem are being tried out at the Technical University in Warsaw. A. Degler is attempting to produce aggregates from pulverised fuel ash (PFA). Poland's coal-fired power stations (like those in the UK and USA) produce vast quantities of PFA and although some of this can be used as a pozzolanic cement substitute it would be best to convert it into aggregate. Degler's investigations on pelleting and extrusion processes have shown that it is possible—but there are delays in designing and constructing the necessary industrial capacity for the actual production. One of the nine major problems is that of environmental protection, so that if ways of using waste as aggregate can be found, two of the major problems will be alleviated.

Halina Badowska at the Technical University is attempting to find ways of utilising waste material from fertiliser

Maria Szekeley is a lecturer in the Department of Biochemistry at Imperial College, London.

THE rabbit globin mRNA sequence differs in various respects from the known nucleotide sequences of prokaryotic messengers. The latter contain a purine-rich tract near the initiation site, about 10 nucleotides towards the 5' end, which can form several base pairs with a pyrimidine-rich region at the 3' end of bacterial 16S RNA. No stable base-pairing is indicated between the 5' non-coding sequence of globin mRNA. A possible site for interaction of these RNAs was found around the initiation codon: here 6 base pairs could be formed. This, however, would imply that the initiator tRNA and the ribosomal RNA compete for the same

sequence in the mRNA.

The 53-nucleotide long non-coding sequence at the 5' end does not suggest formation of stable hairpin loops, but may allow base pairing with a stretch in the 3' noncoding region. A secondary structure which brings together the 5' and 3' ends of mRNA may be relevant to the control functions of the untranslated regions.

The 3' noncoding region is 95 nucleotides long. It shows extensive homology with the human β -globin mRNA. The human sequence has, however, an addition of 39 nucleotides which may have arisen by gene duplication.

I. J. Smalley is a lecturer in the Department of Civil Engineering at the University of Leeds.

production to make building blocks. Gypsum is the critical raw material and blocks using a form of gypsum cement and a polystyrene filler have been produced. A complex programme is also under way to develop resin materials as cements. There is in fact quite a severe shortage of Portland type cement in Poland although ironically enough Polish cement is exported. The need for foreign exchange is deemed greater than the need for cement.

G. Chrabczynski has been particularly concerned with the production of cement building units in which the hydration is accelerated by heating. This is often done under pressure in an autoclave but Chrabczynski has successfully developed methods which do not need the slow and expensive autoclave stage. Concrete railway sleepers with adequate strengths have been produced using much less cement than normal. Success, however, has been at the pilot plant level. There remains the difficult problem of organising factory production of the new items. Research is going on in Chrabczynski's section on organisation and management at all levels in the prefabricated building

block industry and it seems that, unless the persistent organisational problems are solved, the technical advances made in the laboratories will not benefit those who need project 5 to succeed.

It is ironic and regrettable that the new showpiece hotels in Warsaw have had to be built by Swedish contractors. These are certainly impressive buildings but it is a pity that desperately-needed foreign exchange had to be used to build hotels to give foreign businessmen and tourists the opportunity of returning the money to Poland. Project 5 is paradoxical in many ways. The population has recently passed 34 million—a level it reached for the first time just before the war, so that the colossal population losses have been replaced but the housing stock lags. Should family apartments have absolute priority or should the national construction industry be used to stimulate overseas trade? Major economic decisions will affect project 5: it is to be hoped that they will not have too adverse an effect. The 'fifth problem' does not have the scientific glamour of a possible cure for cancer but the Polish people would welcome its solution. □

New calculation of the nucleon optical potential

from P. E. Hodgson

THE differential cross section and polarisation for the elastic scattering of nucleons by nuclei can be very well described by a complex potential: the real part refracts the incident waves and the imaginary part absorbs them, just as a light wave is refracted and absorbed by a medium of complex refractive index. The absorbing potential takes account in a global way of all the reactions that remove flux from the elastic channel.

Unfortunately the potential describing the scattering is not unique: it is frequently possible to find several different potentials that fit the same data. This is unsatisfactory because these potentials give different wavefunctions, and unless we know which is correct it cannot be safely used to calculate the cross sections of non-elastic processes such as inelastic scattering and nucleon transfer reactions.

In principle the ambiguities between the potentials can be resolved by calculating the potential from more fundamental data, in particular from the nucleon-nucleon interaction,

together with the structure of the target nucleus. In practice, however, this is difficult due to the many-body nature of the problem.

Over the past few years there have been many attempts to calculate the optical model potential. These differ in the choice of approximations made to simplify the calculations and they give results in fair agreement with the experimental data. Particularly encouraging work has been carried out by Jeukenne, Lejeune and Mahaux of the University of Liège, who have been able to account for the volume integrals of the optical potentials (*Nature* **253**, 163; 1975).

Recently a new approach to this problem has been made by Brieva and Rook of the University of Oxford, and some preliminary results were reported at the Conference on Nuclear Structure at Tokyo in September. They start from the Hamada-Johnston potential that gives an accurate fit to the nucleon-nucleon scattering data, and then solve the Bethe-Goldstone equation for the motion of nucleons in infinite nuclear matter subject to this potential. This gives a quantity called an averaged *t*-matrix that is used to obtain the

optical potential by folding with the nuclear density distribution, using

$$V(r) = \int p(r') t(|r-r'|) dr'$$

with addition of exchange terms.

In this calculation the approximations were carefully chosen to facilitate the calculation without too much loss in accuracy. It differs from most previous work in giving both the real and imaginary parts of the optical potential, and allows the radically-dependent *t*-matrix to be non-local and energy-dependent. The spin-orbit potential is also calculated and is found to be very similar to the phenomenological spin-orbit potential.

The optical potential they calculated for ^{40}Ca is shown in Fig. 1 and compared with the phenomenological potential that gives the best fit to the differential scattering and polarisation data. It is particularly notable that the calculated real potential does not have the same radial shape as the phenomenological Saxon-Woods form. This indicates that this very frequently-used analytical form of the potential may not always be adequate. The calculated imaginary potential shows considerable structure, partly due to the form of the nuclear density distribution and partly due to the self-consistency requirement imposed on the potential. The differential cross section and polarisation calculated from these potentials are shown in Fig. 2. The agreement is strikingly good, indicating that it is now possible to calculate optical model potentials that give fits to the data that are comparable in quality to those found with phenomenological poten-

Fig. 1 Real and imaginary parts of the optical potential for protons on ^{40}Ca calculated from the nucleon-nucleon interaction compared with the corresponding phenomenological potentials.

Fig. 2 Differential cross section and polarisation for the elastic scattering of 30.3 MeV protons by ^{40}Ca compared with optical model calculations using the calculated potential.

tials with many adjustable parameters. In some respects they are even superior as they can give features of the cross sections that cannot be explained by phenomenological potentials.

This work is very promising, and needs to be extended and applied to a range of nuclei to enable its validity to be explored. It should also prove possible to extend the method to the calculation of the optical potentials appropriate to composite particles such as deuterons and alpha particles, and perhaps also to heavy ions. The availability of optical potentials that can be reliably calculated from fundamental data instead of being obtained by phenomenological analyses of elastic scattering data will be of the greatest value in nuclear structure studies. □

A hundred years ago

THE question has been discussed of late whether the ancient Greeks had an acute and true sense of colour. I remember once to have seen the remark that Sophocles shows his want of colour-sense by speaking of wine-coloured ivy. Now this really shows how true his perception of colour was. I enclose two ivy leaves which I have gathered to-day off a wall; I could have gathered plenty of the same colour, which, as you see, is claret colour.

Modulation of hormone receptors

from J. R. Tata

It is now widely accepted that receptors for hormones and other cellular signals, whether located on the cell's surface or intracellular, turn over rapidly so that the modulation of receptor level can be an important element regulating a cell's activity. About two years ago an account of the first reports on the possibility that some hormones themselves may control the levels of their own receptors or receptors for other hormones appeared in these columns (*News and Views* 257, 741; 1975). Whereas autoregulation of hormonal receptors is still a matter of some controversy, many investigators now accept that one hormone can regulate the level of receptor for another. In some instances it is hard to see the physiological relevance of such interplay among hormones but a recent paper suggests that it may be of clinical significance.

Endocrinologists and cardiologists have for long been aware of the tachycardia accompanying hyperthyroidism or thyrotoxicosis and that cardiac function in such patients was abnormally sensitive to small changes in adrenaline levels. Williams *et al.* (*J. biol. Chem.* 252, 2787; 1977) now explain this well-known syndrome by suggesting that thyroid hormones regulate the number of adrenergic receptor molecules in cardiac cells. In a carefully designed experiment they used the binding of the potent β -adrenergic antagonist (—)-dihydroalprenolol, to compare the number and affinity of β -adrenergic receptors in membranes isolated from myocardium of normal rats and animals made hyperthyroid by injections of the two thyroid hormones, L-thyroxine and triiodo-L-thyronine. Within 3–7 days, this treatment caused an increase in the binding capacity of cardiac membranes from 89 fmol of (—)- ^3H -dihydroalprenolol per mg protein in normal (euthyroid) rats to 196 fmol per mg protein. On the other hand, there was no difference in the affinity of the receptor for dihydroalprenolol or the β -adrenergic agonist isoproterenol (K_D at equilibrium of 2–15 nM dihydroalprenolol) between membrane preparations from euthyroid and hyperthyroid animals. Williams *et al.* therefore conclude that thyroid hormones control the number but not the nature of β -adrenergic receptors in myocardial cells. This would explain the tachycardia and increased myocardial contractility in clinical hyperthyroidism. Their observations would

J. R. Tata is at the National Institute of Medical Research, London.

also explain an earlier report that cultured foetal mouse hearts were rendered more sensitive by triiodothyronine to the chronotropic effect of β -adrenergic receptor stimulation (Widenthal *J. Pharmacol. exp. Therap.* 190, 272; 1974). If the same were true of other cells, then these findings could also explain skeletal muscle tremor or the enhanced rate of glycogenolysis and lipolysis in hyperthyroid subjects or experimental animals.

Are the observations of Williams *et al.* merely a peculiarity of thyroid hormones or are they part of a general pattern of an interhormonal regulatory device? Several recent publications point to the latter possibility. Such evidence comes mainly from studies on the interaction between hormones regulating reproductive processes which are known to be under multiple hormonal control. To cite but a few examples, Charreau *et al.* (*Molec. Cell Endocrinol.* 7, 1; 1977) have put forward a novel explanation why androgen, which like other steroids is not thought to act on adenylate cyclase, causes an increase in cyclic AMP levels in the rat prostate. These workers found that dihydrotestosterone (the active form of testosterone in target cells) increases the number of receptors for prolactin, a hormone known to influence male sexual development and to have a marked effect on adenylate cyclase in other tissues such as the mammary gland. Any interpretation of long-term studies of this kind in whole animals suffers from the drawback that one may not be measuring direct effects of hormones on receptor levels. For this reason, the demonstration that FSH (follicle stimulating hormone) induced receptors for hCG (human chorionic gonadotropin) directly *in vitro* in rat granulosa cells (Nimrod *et al. Nature* 267, 632; 1977) is significant. Hormonal interplay can of course operate in both directions, namely that one hormone can also dampen the sensitivity of a cell to another. Thus, it is interesting to note a recent report by Bhakoo and Katzenellenbogen (*Molec. Cell Endocrinol.* 8, 121; 1977) in which progesterone is shown to suppress the synthesis of oestrogen receptor molecules in the uterus. The resulting suppression of the replenishment of receptor molecules would thus explain the lowered uterine sensitivity to oestrogen that is known to be provoked by progesterone.

It is not difficult to predict that we shall be seeing many more examples of hormonal modulation of hormone receptors, particularly in reproductive tissues, mammary gland and the neuro-endocrine complex, where multiple hormones are involved in the regulation of their development or adult

functions. The question then arises as to whether modulation of receptor levels is restricted to interhormonal regulation or whether this phenomenon is even more widespread. Raff (*News and Views* 259, 265; 1976) has reviewed the general topic of regulation of receptors, particularly where it concerns immunological sensitivity and lymphocyte maturation. A recent paper from Munck's group (Smith *et al.* *Nature* 267, 523; 1977) is therefore significant in this context since it suggests that non-hormonal signals could also modulate hormone receptors. These workers studied glucocorticoid receptors during mitogen (concanavalin A) stimulation of human lymphocytes and noted that blast transformation and mitosis is associated with a striking increase in the number but not nature of receptor sites per cell. How such a modulation of receptor numbers is brought about remains unknown, but their observations explain quite nicely the increased sensitivity to glucocorticoid hormones known to be brought about by mitogenic stimulation of lymphocytes and may also be relevant to the general question of how steroid hormones control the immune response. □

Pollen analysis at INQUA

from Paul Colinvaux

The X INQUA Congress was held in August, 1977 at the University of Birmingham. Pollen analysis was one of the many topics bearing on Quaternary research that were discussed.

FOR most of its existence, pollen analysis has been a tool of other disciplines; being used to age strata, to supply the temperatures of past times, to serve phytosociologists as they mapped the supposed movements of plant associations through millennia.

Time stratigraphy is now provided by Quaternary geology and isotope chemistry. Oceanic sediments now provide maps of past global climates. The press of contemporary ecological theory is to question strongly the validity of many former ideas about the integrity of plant communities. These developments allow pollen analysis to be used in more exhilarating ways, and the new ways are now taking hold.

One group of pollen analysts is interested in the ancestry of the remarkable complexity of the deciduous forests of Eastern North America. For several years this school has been

growing more confident in its insistence that the forest associations of Eastern America are comparatively recent assemblages of plants without the integrity, or persistence as communities, required by classical plant sociology. This school has used the pollen record to infer the responses of plant populations to known climatic change, borrowing climatic data from other disciplines. At the conference these analysts were confident that their case is made. Pollen analysis shows that plant associations beyond the front of the Wisconsin ice were different from all the associations we know today; and the tundras, prairies, and forests that replaced each other on the lands once held by ice were always critically different from the modern assemblages.

However, INQUA also saw reports of the refined use of pollen data to infer past climates. Fossil pollen assemblages are being compared with many surface samples, and the data are then being analysed with multivariate statistical techniques. It sounds like using principal components and canonical series to do what was once done by eyeball fits, but the approach is vitally different. The old way was to seek modern plant associations that were homologous with past communities and to graft on to those past communities the climate under which the supposed modern homologue was living. The new way is to select from ancient pollen spectra only those taxa found in comparable numerical abundance in surface samples, and then to compare the distributions of this select array with distributions of the same plants in historic times. There is in this no dubious assumption about the integrities or environmental requirements of whole plant communities; the only biological assumption is the respectable Darwinian one that niche requirements of each species do not change very much. Climatic reconstructions of this kind follow the methods that have been used by students of foraminifera in deep sea cores to reconstruct ancient water temperatures. INQUA saw several elegant papers using this approach. At INQUA, therefore, pollen analysis was used both to refute the existence of permanent plant communities and to improve the resolution of the climatic inferences that can be drawn from pollen.

All pollen analysts at INQUA drew comfort from the certainty that the oxygen isotope record of deep sea cores yields a chronology of the volume of global ice. The isotope record is not of ocean temperature, as was thought only a short while ago, but of glacial ice. It tells us nothing about world climate, other than the existence of ice itself, but it is a global time stratigraphy and

it must loosely relate to the particular climate of any one place. All pollen analysts have found themselves asking 'Are the local developments of vegetation that I see in step with the curve defining relative ice volume?' INQUA saw the first data relating isotope measurements to pollen in the same samples of offshore cores, revealing a gratifyingly close synchrony between changes in coastal forests and the volume of distant glaciers. A climatic linking mechanism is inescapable.

There were the expected developments in longer records and explorations in lesser-known parts of the world. Those with the long cores will look to the ice-volume curves to help with their time-stratigraphies and the first attempt of this kind to date long cores with the help of the ice volume curve was reported—a splendid long record from Searls Lake in California. The still very uncertain possibilities of remanent magnetism are also being explored to date pollen records back to the postulated Blake Event and beyond at Japanese Biwa, in Alaskan Imuruk Lake, and for the superb section from Grande Pille in France. The next INQUA may well see some ambitious reconstructions from these places describing the shufflings of plant species on single sites for more than 100,000 years.

The number of pollen records from the rest of the world grows slowly but steadily. Mapping the past in the Soviet Union continues as pollen analysts follow the completed map of the Quaternary deposits of that vast country, taking particular note of regions where archaeologists are active. But in lower latitudes where we need to know most there is still least to report. From the Indo-Pacific there are a few scattered records but from the South American equator near silence, particularly from the Amazonian basin. A member of the CLIMAP team at INQUA was heard to remark that he had had to infer the Wisconsin age vegetation of Amazonia from a paper on the modern distribution of bird species.

Yet in Africa there is progress, as papers come from Ethiopia and Chad, the lakes of the Rift, the dry basins of Sahara, and an array of stations in the South. But this African work shows how formidable are the difficulties of pollen analysis in tropical regions where the crucial species leave little pollen and where the species list is huge. As D. A. Livingstone remarked, deep in Tanganyika and the other lakes of the Rift lies a detailed history of the vegetation of this cradle of humanity since the Pliocene and beyond, but he despaired of seeing it read in his lifetime. □

review article

Claims and accomplishments of applied catastrophe theory

Raphael S. Zahler* & Hector J. Sussmann†

Several representative attempts to apply catastrophe theory to biological and social science problems turn out on close analysis to be characterised by incorrect reasoning, far-fetched assumptions, erroneous consequences, and exaggerated claims. Catastrophe theory seems to have made no significant contributions to biology and the social sciences, and to have no advantage over other better-established mathematical tools which have been used to better effect.

EMBRYOLOGY, ethology, ecology, and geology; physics, economics, dynamics, and linguistics; prison riots, literary symbolism, and the Vietnam war—these are some of the subjects to which catastrophe theory is said to be applicable. Its novel mathematical apparatus seems to be a near-universal tool, according to its proponents: "Properly understood and exploited, this ever-expanding web of concepts promises mankind a unique weapon against ignorance and a profound insight into the universe"¹.

We disagree. And because we feel that the many researchers now being attracted to catastrophe theory stand to gain nothing but disappointment and wasted time, we have written a critical study of applied catastrophe theory². Our conclusion is that the claims made for the theory are greatly exaggerated and that its accomplishments, at least in the biological and social sciences, are insignificant.

This is because catastrophe theorists have misused the basic mathematics in ways that lead to incorrect reasoning; they have offered models which are based on unreasonable assumptions and which lead to erroneous conclusions; and they have made predictions which are either vacuous, tautologous, vague or impossible to test experimentally. We do not say that catastrophe theory cannot possibly be applied. There may be legitimate uses in areas of physics and engineering, and some have suggested that the use of topological methods will be conceptually stimulating to researchers. So far, however, its record is poor.

We stress that we are not discussing the correctness or importance of catastrophe theory as a purely mathematical subject: we are sceptical only about its usefulness as a tool for extramathematical applications. We present this critical picture because we are excited about the prospect of new applications of mathematics, and concerned that many will be disenchanted with all of modern mathematics when they discover, as we have, that catastrophe theory is a blind alley.

This article is organised round a list of ten main kinds of defect found in catastrophe theory models in biology and social science. Each is illustrated briefly by one or two examples. For more detail, the reader should consult our longer paper². We are grateful for the advice of R. FitzHugh, J. C. Scanlon, H. Othmer, C. S. Hui, B. Goodwin, J. Sturtevant, G. Velicelebi,

S. Mabrey, J. F. Chlebowski, E. S. Crelin, J. F. G. Auchmuty, N. Van Arkel whose comments have been of great help in the preparation of this paper.

The cusp catastrophe

Most applied catastrophe theory is based on the 'cusp catastrophe' (Fig. 1). In this picture, the horizontal plane represents the possible values of two control parameters a and b , and the behaviour of the system is plotted on the vertical x -axis. For example, suppose we place a globular protein in solution and study its denaturation in terms of the concentration a of a denaturant and the temperature b . The extent of denaturation x_0 (as measured by the negative of the optical rotatory dispersion) as a function of denaturant concentration a_0 and temperature b_0 can be plotted as a point in the vertical line through (a_0, b_0) ; all such points form the curved 'cusp' surface shown, according to Kozak and Benham³.

So far this is just standard analytical geometry. The alert reader, however, may have noticed that above each point (a_0, b_0) in the shaded region R of the control plane lie not one but three different points of the behaviour surface; which one represents the actual behaviour at (a_0, b_0) ? The answer, given by the delay rule, is that it depends on how (a_0, b_0) is approached. As a and b vary continuously, x is to vary continuously in the cusp surface as long as possible. When continuous variation of x is not possible, then x is to jump to another sheet of the surface. For example, suppose the control parameters vary in such a way that the point (a, b) moves from Q_1 to Q_2 along the path P_1 , shown in Fig. 1. Initially, there is only one point in the cusp surface lying above each point in P_1 , so we follow the line shown from Q_1 towards J . Even when we pass point J the delay rule keeps us on the bottom sheet. But, when we reach point K , we must jump to K_2 on the upper sheet as shown. This is how sudden changes of behaviour in response to smooth changes of controls occur in catastrophe theory models.

Why the cusp? Catastrophe theorists argue that, according to a "deep mathematical theorem" of René Thom, essentially any system where sudden changes occur and where two control parameters appear can be described by the cusp; it is an inevitable, universal paradigm. According to Kozak and Benham, in fact, Fig. 1 correctly predicts the denaturation behaviour of RNase or collagen subject to the influence of temperature and CaCl_2 concentration. For example, following path P_1 from Q_2 to Q_1 , or P_3 from Q_3 to Q_4 gives a sigmoid curve for x , which corresponds to the appropriate experimental data. By distorting the cusp M somewhat (which is permissible

*104 Hubinger Street, New Haven, Connecticut 06511.

†Department of Mathematics, Rutgers College, Hill Centre for the Mathematical Sciences, Busch Campus, New Brunswick—New Jersey 08903.

the data or (2) purely unverified hopes, or (3) independent of CT or (4) just wrong.

Consider, for example, Zeeman's studies of how homogeneous tissue of an embryo differentiates into two types separated by a frontier, a phenomenon he calls divergence or differentiation². The 'main theorem' of this paper is worth quoting in full: "Homeostasis, continuity, differentiation, and repeatability imply the existence of a primary wave. In other words a frontier forms, moves and deepens, then slows up and stabilises, and finally deepens further".

It is hard to imagine what we could learn from such a breath-takingly vague statement, but we need not ponder this very long, since its proof is wrong as well.

Misuse of genericity

For one thing, the surface eventually chosen to model the cellular differentiation is not dictated by Thom's theorem but is obtained by a series of arbitrary choices which are justified—if at all—by appealing to 'genericity'. This mathematical concept is a way of excluding 'exceptional' or 'degenerate' cases. (For instance: 'generically, the axes of an ellipse are not equal' means that circles are an exceptional class of ellipse or, more intuitively, that a 'randomly chosen ellipse' is quite unlikely to be a circle.) In the course of his proof, Zeeman arbitrarily translates the vague word 'repeatability' into the precise concept of genericity. But then, all his theorem says is that if nothing exceptional happens, then the frontier moves.

Fig. 2 Distorted cusp catastrophe; see ref. 3, Fig. 2.

Zeeman's 'proof' consists of no more than the observation that, if the frontier did not move, that would be quite exceptional. To evaluate this kind of reasoning properly, notice that the same logic, if correct, would apply equally well not just to frontiers of tissues but to anything whatsoever. So, Zeeman's reasoning 'proves' that everything moves except for those exceptional objects that do not. (For details, see ref. 2 §12 a).

Later in the same paper, Zeeman 'proves' that the frontier moves initially at constant speed. His proof is as follows: the frontier can be replaced initially, to first order, by its tangent, QED. Again, there is nothing in this reasoning that restricts its validity to frontiers of tissues, or to the time when the frontier forms. So Zeeman is really proving that everything moves

at constant velocity. But let us apply the same logic once again. Why not use the second degree Taylor approximation? And why not argue about the acceleration as Zeeman does about the velocity, and conclude that the acceleration is non-zero, because it would be exceptional if it were zero? This gives us the conclusion that everything moves with non-constant velocity.

Finally, why can we not take the zeroth order approximation? The conclusion then is that nothing moves at all.

We see that using these methods, everything, no matter how absurd, can be proved.

More than two thousand years ago, Zeno formulated his celebrated paradox of the arrow. Consider an arrow in its flight. 'At each instant of its flight the tip of the arrow occupies a definite position. At that instant the arrow cannot move, for an instant has no duration. Hence, at each instant the arrow is at rest. Since this is true at each instant, the moving arrow is always at rest. This paradox is almost startling. It seems to defy logic itself.'

The development of Calculus has resolved this paradox, and taught us how it is possible for things to change and, at the same time, be what they are at each instant. The position of the tip of the arrow is what it is at each time, but it is different at different times. Hence the arrow can have a definite position at each time, and not be at rest. What is true of the position is also true of velocity. The velocity has a value at each point, but this does not mean that it is constant. Zeeman, a Twentieth Century Zeno, is reformulating the paradox as a corollary, thus ignoring more than two millennia of mathematics.

But Zeeman's main theorem is wrong for other reasons as well: it is easy to show by means of counter examples that Zeeman's conclusions that the frontier does not stabilise or deepen do not follow from his assumptions. When these counter-examples were brought to the attention of catastrophe theorists, the theorem was defended by disclosing new interpretations of the terminology and the hypotheses. For instance, the hypothesis of 'differentiation' is now taken to mean that after some time two different types of tissue are found and no more changes occur. If so, then after some time the frontier no longer moves, so the frontier does indeed stabilise. But of course this 'proof' of stabilisation is transparently circular.

In general, the hypotheses on which many catastrophe-theory arguments are based are often vague. When terms like 'differentiation' and 'repeatability' are used without any precise translation, the correctness of the 'proofs' is hard to assess. Catastrophe theory papers consistently violate one of the most basic rules of the scientific method: state clearly what you mean and do not change definitions in the middle of your reasoning.

Misleading use of mathematics

The most basic criticism of Zeeman's catastrophe theory of embryology, however, is the way the mathematical foundations are used. Others have pointed out that the 'deduction' that differentiation will occur as a pattern of primary and secondary waves arises not from catastrophe theory itself but from the conditions assumed to exist before the primary differentiation process begins (for example a gradient of cell states). In fact, then, most of the results of this paper, regardless of their merit, have nothing to do with catastrophe theory at all.

To see why this is important, we must remind the reader of what catastrophe theory is and is not. First, events in which apparently 'catastrophic' changes occur are not necessarily 'catastrophes' in the technical mathematical sense. Catastrophe theorists agree that the term 'catastrophe' is reserved for certain kinds of singularity of smooth maps, seven of which have been described and classified elegantly by Thom. The keystone of catastrophe theory, in fact, is Thom's profound theorem. It is what is supposed to give catastrophe theory its deductive powers, because it allows one to conclude that a given situation must be represented by a cusp, or one of the other elementary catastrophes.

As we have illustrated, however, most catastrophe theory models make no use of Thom's theorem. Thus the cusp is no longer inevitable or unique.

How, then, does the cusp arise? Often, as in the embryology models, the cusp arose because the hypotheses were carefully chosen to make sure that it would. In other cases, however, experimental data are plotted and found to resemble a cusp^{3,8}. This is not surprising: if we plot an ordinary hysteresis loop in

Fig. 3 Hysteresis loops of decreasing size.

two dimensions (Fig. 3a), in which fast vertical jumps alternate with slower horizontal movements, and then imagine a continuum of such loops getting smaller (Fig. 3b) and finally vanishing to form a continuous curve (Fig. 3c), we get a surface resembling the cusp of Fig. 1. Thus we can regard the cusp as a nice way of picturing a system with variable degrees of hysteresis. But it is certainly not unique in this: a surface with a double fold whose projection was any smooth curve (a parabola, for example: see Fig. 4) would do as well. So we must ask again: what is special about a model that looks like a cusp? Although some have found such pictures aesthetically satisfying, or a source of insight, we can only state that the fact that certain data happen to form a cusp-like shape tells us nothing new about the system.

Careless discussion of evidence

Catastrophe theorists have asserted that there is experimental evidence for some of their models. For instance, Zeeman⁴ writes, "I have constructed CT models of the heart beat, the nerve impulses and the formation of gastrula and of somites in the embryo. Recent experiments by J. Cooke and T. Elsdale appear to confirm some of my predictions". The facts are as follows. (1) No experiments have been made to test the predictions of Zeeman's nerve impulse models. As for the heart-beat, Zeeman is said to have made experiments in 1972, but the results have not been published (Zeeman, personal communication). (2) The catastrophe theory nerve impulse models disagree with experimental voltage-clamp data⁹ in several important aspects, deny the universally accepted concepts of the sodium leak and the independence of sodium and potassium channels, and lead to the wrong propagation speed for the action potential. (3) Zeeman's embryology paper⁵, besides being mathematically wrong, betrays the author's inexperience in embryology. For example (p. 27), Zeeman likens the embryonic neural tube to a roll of stiff paper which tries to maintain its curl. But experiment shows that cut neural tube persistently tries to unroll¹⁰. (4) T. Elsdale *et al.*¹¹ write: "... we do not yet conclude that the observations here presented have confirmed Cooke and Zeeman's model to the exclusion of others". (5) J. Cooke (personal communication) writes: "I, at least, do not regard any of the predictions of the model in which I am involved as being deeply distinctive to catastrophe theory".

Stewart¹ repeats the untrue assertion that Zeeman's embryology predictions have been "recently verified by experiment". Regarding the use of catastrophe theory in social sciences, Stewart writes: "Although most such models still lack precise data, an interesting exception is a study by Zeeman and several collaborators of how tension and alienation among prison inmates influence disorder. A cusp catastrophe fits the data

very well, the sudden jumps being riots and truces". In fact, when Zeeman and his coworkers plot points in a plane, and look for a cusp curve which fits them, they do not succeed in fitting one curve, so they use two, and claim that the cusp must have moved during the process. Finally, they do not use any statistical techniques to determine whether or not their pair of cusp curves gives a good fit (compare Fig. 5).

Dixon Jones⁸ has made a catastrophe theory model for budworm infestation. His model relies on a 'cusp' which is really not a cusp in the correct mathematical sense. His model predicts a fast rise of a variable, but the data rise slowly. Jones then rescues his model by making a logarithmic change of scale!

At this point the reader may suspect that we have chosen the weakest catastrophe theory papers as targets for our criticism. The contrary is true: the best biological applications are contained in the papers just cited. Others^{12,13} consist of long expositions of the mathematics of catastrophe theory, copious explanations of elementary biology, and vague speculations on how the two could be brought together.

Unreasonable or ambiguous hypotheses

Isnard and Zeeman¹⁴ have a model for how a country makes decisions about going to war. It is assumed that public opinion depends on the 'cost' of the war, and the (perceived) 'threat' posed by the enemy nation.

Among the five hypotheses of the war model are: Hypothesis 2: If the cost of the war is low, then opinion will be unified, and the greater the threat, the greater will be the level of military action called for.

Hypothesis 3: If the cost is high, and the threat moderate, then opinion will be split between doves and hawks.

Now in a given conflict situation, no sensible person would advocate a level of military action so low that the enemy is sure to win an easy victory. Either one wants no war at all, or

Fig. 4 A folded surface which is not a cusp since the projection of the fold curve on the control plane does not have a sharp point.

one wants to use as much military force as he thinks is needed to win. (War will follow when at least one side miscalculates, and both sides think they can win.) So, the dichotomy war—no war is a discrete one, and this is so whether the cost is high or low. But, if this is taken into account, we are left with a better theory which, however, does not involve a cusp.

Not only are the hypotheses of the war model unreasonable but they do not lead to the conclusions reached by the authors. Their main claim—that the hypotheses imply, via Thom's theorem, that the behaviour set is a cusp surface—is once again dubious, since the proof, which is not given, is presumably

ingless. The same reasoning applies to the 'level of military action' in the war model, as we have shown.

Better alternatives

Defenders of catastrophe theory claim that it provides, for the first time in history, a mathematical method for modelling discontinuous phenomena. This is false because, as we have shown, catastrophe theory does not lead to satisfactory models. But it is also false because it ignores the whole body of discrete mathematics, the study of shock waves, bifurcation theory, and the mathematics of quantum mechanics. Better alternatives certainly exist.

Besides, no mathematical theory, no matter how elegant it may be, can serve as a substitute for the hard work of learning the facts about the world. Catastrophe theory is one of many attempts that have been made to deduce the world by thought alone. It offers to mathematicians "the hope of applying mathematics without having to know anything but mathematics"¹⁶. An appealing dream for mathematicians, but a dream that cannot come true.

Appeal of the theory

Why has catastrophe theory acquired such widespread popularity? One possible reason may be its impressive claims of universality and usefulness, backed up by a large number of (mostly unrefereed) publications praising each other extravagantly; another might be the unusual nature of the mathematics used, combining concepts that are completely inaccessible to anyone who is not a professional mathematician with the use of some pictures of amazing simplicity, so that the result is simple to grasp intuitively but difficult to criticise.

It may be said that catastrophe theory is a new theory and that, while all the applications proposed so far have serious flaws, each one has benefits that make it worthwhile. Our criteria for judging a theory (or method) are rather generous. Even if a theory rests on questionable assumptions, or is based on faulty reasoning, or leads to false conclusions, or deals with ambiguous concepts, or does not make true testable predictions, we are ready to accept that it may be valuable, so long as it does not have all these faults at once.

The catastrophe theory models that we have examined, however, combine all these faults. The assumptions on which they are based are unreasonable and/or vague. The reasoning used to draw conclusions from the hypotheses is mathematically incorrect. The conclusions are either trivial (for example "a frightened dog, if angered, may attack"⁴) or false.

The possibility that, in the future, catastrophe theory may produce solid applications, cannot be dismissed *a priori*. However, its spectacular failures should suffice to raise serious doubts. For a method that has been said to have "the potential for describing the evolution of forms in all aspects of nature", existing evidence is indeed disappointing. The scientific community must remain sceptical until the proponents of catastrophe theory succeed in substantiating their claims. The burden of the proof is on them.

Fig. 5 The 'analysis of the data' of the paper by Zeeman *et al.* on prison riots¹⁷. These data are supposed to show that a cusp catastrophe gives a good fit.

based on some translation (also not given) of the vague hypotheses into precise language. It is not hard to show, however, that depending on one's interpretation of the hypotheses, either the conclusion does not follow; or the result does not depend on Thom's theorem, and is essentially contained in the hypotheses.

In fact, the only possible part Thom's theorem might play is to exclude a rounded bifurcation curve (such as the parabola of Fig. 4) in favour of a cusp (Fig. 1). But since either Fig. 1 or Fig. 4 would lead to the conclusions stated by Isnard and Zeeman, there is really no need to use Thom's theorem after all.

Spurious quantification

Catastrophe theorists often attempt to make a discrete variable into a continuous one so that CT can be applied. In Zeeman's dog aggression model⁴, for example, the level of aggression of a dog is considered as a continuous variable x , ranging "from outright retreat through cowering, avoidance, neutrality, and growling and snarling to attacking". He also states, however, that an 'attack catastrophe' occurs when the value of x jumps upwards from one sheet of the behaviour surface to another. Despite this ambiguity, it can be shown that with either interpretation the attack is embedded in a continuous family of behaviours. But this is absurd: the idea of a 'semi-attack' by a dog, or of a snake gradually attacking a person, is utterly mean-

Radio structure of 3C147 determined by multi-element very long baseline interferometry

P. N. Wilkinson & A. C. S. Readhead

Owens Valley Radio Observatory, California Institute of Technology, Pasadena, California

G. H. Purcell*

National Radio Astronomy Observatory, Charlottesville, Virginia

B. Anderson

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, UK

We have determined the radio structure of the quasar 3C147 from multi-baseline VLBI data at 609 MHz using both a conventional method and a technique which uses the 'closure' phase information to produce a good approximation to a synthesis map of the source. The structure is similar to the central part of M87, with a bright core and a linear 'jet' of projected length ~ 1.5 kpc which is concentrated in bright 'knots'.

THE quasar 3C147 ($z = 0.545$, $V \simeq 17$ m) is one of the more intense radio sources in the sky at decimetre wavelengths. Previous interferometer and interplanetary scintillation observations¹⁻⁶ have shown that its radio emission is confined to a region $\lesssim 1.0''$ in extent. At high frequencies most of the radiation comes from a complex region of the source $\lesssim 0.2''$ in size, while at low frequencies ($\lesssim 100$ MHz) the size of the predominant emission region is $\sim 0.7''$. The interferometer observations, in which only fringe amplitudes on single baselines were measured, were inadequate to determine in any detail the morphology of the compact region. We report here the results of more extensive observations which do reveal this structure in considerable detail. They constitute the most reliable complex radio structure determined by VLBI techniques.

The observations

The data were obtained in two independent observing runs, both at 609 MHz, using circularly polarised primary feeds on each antenna. In each case the data were recorded with NRAO MkII VLB equipment and the video tapes correlated on the NRAO processor⁷. The details of the telescopes used and their rf performance are given in Table 1. The six interferometer baselines are shown schematically in Fig. 1a, and the resolution achieved by each interferometer pair as a function of hour angle is shown in Fig. 1b.

The first observations, made in December 1973, involved only the three US stations (giving the three inner tracks in Fig. 1b) and were analysed solely by G. H. Purcell in 1974. The plots of fringe amplitude as a function of interferometer hour angle are shown in Fig. 2a. Further observations of 3C147 were made, using all four telescopes, in March 1975. We observed the source for nearly all the time for which it was jointly visible at each station in order to obtain the maximum possible 'closure' phase information, as well as visibility amplitudes.

A closure phase, C , is formed by the addition of the observed interferometer phases around a closed loop of baselines at a given time. The simplest loop is a triangle. Four triangles can be formed from our four station network (see Fig. 1a), but only three of these yield independent information. On each baseline we measured the fringe phase, ϕ_i , given by

$$\phi_i = \psi_i + \theta_i$$

where ψ_i is the phase of the visibility function and θ_i is a

Fig. 1 a, Schematic representation of the six interferometer baselines. We formed closure phases around all four triangles but used mainly C_{123} , C_{245} and C_{346} (see text). b, The baseline of each interferometer as a function of hour angle. The source was observed continuously along each track. The baselines are as follows: 1, Ft Davis-OVRO; 2, NRAO-Ft Davis; 3, NRAO-OVRO; 4, J. Bank-NRAO; 5, J. Bank-Ft Davis; 6, J. Bank-OVRO.

*Present address: Jet Propulsion Laboratory, Pasadena, California

perturbation due to changes in the path delay to each telescope through the atmosphere and ionosphere, to phase drifts in the independent local oscillators and to uncertainties in the baseline and source position. A combination of these effects, with the ionosphere having a dominant role at this relatively low frequency, precludes the direct use of the six interferometer phases. It has been shown^{8,9} that in the closure phase the perturbations cancel, and thus the three closure phases we form

$$C_{123} = \phi_1 + \phi_2 - \phi_3$$

$$C_{245} = \phi_2 + \phi_4 - \phi_5$$

$$C_{346} = \phi_3 + \phi_4 - \phi_6$$

are equivalent to

$$C_{123} = \psi_1 + \psi_2 - \psi_3$$

$$C_{245} = \psi_2 + \psi_4 - \psi_5$$

$$C_{346} = \psi_3 + \psi_4 - \psi_6$$

respectively. The three closure phase curves we obtained are shown together with the six fringe amplitude curves in Fig. 3a, b and c. Unfortunately, because of a malfunction in the NRAO processor, the signal-to-noise on all baselines except NRAO-Ft Davis was reduced by a factor of two from the normal value.

The agreement between the independently measured fringe amplitude curves for the US baselines at the two epochs is within the expected uncertainty due to receiver noise and calibration errors (~5%). This agreement shows that there have been no significant changes in the structure of the source during an interval of 15 months¹⁰.

The brightness distribution

The brightness distribution of the source was inferred by Purcell from the 1973 amplitude data alone, using a model fitting method in which the parameters of elliptical Gaussian components are adjusted by an iterative procedure to produce a best fit to the data in the least squares sense. The complexity of this source is such that 13 gaussian components were required to produce the solid lines in Fig. 2a, which are the fringe amplitudes calculated from the final model. We do not list the parameters of this model, but rather display the contours of radio brightness which they represent; this 'picture' of 3C147 is shown in Fig. 2b. Note that because no phase information was included there is a 180° ambiguity in its orientation.

To analyse the more extensive 1975 data we devised a new approach which is an extension of the following scheme proposed by M. H. Cohen: beginning with a model of the source based on amplitude data alone, calculate the visibility phase of this model on all baselines and use this phase, with the observed amplitudes, to make a 'map'. Using the CLEAN technique¹¹⁻¹³ reduce the sidelobe level on this 'map' and thereby produce a new model of the source. The phases predicted by this new model are different from the original phases and thus if we repeat the process using these new phases the 'map' will be different from the original one. Iterate, using the new model to predict the phases each time and see whether the method converges to a stable 'map'. This method is essentially that proposed by Fort and Yee¹⁴, except that where we use the CLEAN technique, they set all negative regions of the 'map' to zero at each iteration. We decided to extend the procedure proposed by M. H. Cohen by including the closure phase data, and thus to make use of all the information available in present-day VLBI observations (that is fringe amplitude, closure phase and extent of (u,v) coverage).

Table 1 Interferometer elements

Location	Institution	Diameter (m)	System Noise (K)	Sensitivity (kJy ⁻¹)

Fig. 2 a, Fringe amplitude data on the US baselines in December 1973. Mean error bars shown include a contribution from the uncertainty of the flux scale on the different baselines. The solid lines are the predicted amplitudes from the model in Fig. 2b. b, Contours of radio brightness derived from the 13-component model fitted to the fringe amplitudes in Fig. 2a. The contour levels were chosen to correspond with those in Fig. 4. The original Gaussian components have also been convolved with a circular Gaussian (FWHM = 0.009") to simulate the effect of the 'clean beam' in Fig. 4.

This combination of the closure phase with an iterative 'cleaning' technique has subsequently proved to be a powerful method for determining source structure provided the (u,v) plane is sufficiently well sampled. The method will be described in more detail elsewhere, but the analysis of the 3C147 data provides a simple and illuminating example of its use. It is clear from the fringe amplitude and closure phase plots that this source contains a compact region which is barely resolved on the three longer baselines. It is reasonable to assume that the phase of the visibility function is almost constant and close to zero on these baselines (that is, $\psi_4 \approx \psi_5 \approx \psi_6 \approx 0^\circ$) irrespective of the detailed structure of this region. For each UT interval we can therefore solve the three independent closure phase relationships and determine unambiguously, within the accuracy of our assumption, the true visibility phase on the shorter baselines (that is, ψ_1, ψ_2 , and ψ_3). In this case we are using the compact region as a phase reference.

Note that the phase closure information has enabled us to

Fig. 3 *a, b*, Fringe amplitude data from March 1975. The signal-to-noise ratio on all baselines, except NRAO-Ft Davis, is only one half the expected value (see text). The solid lines are the predicted amplitudes from the brightness distribution shown in Fig. 4 *a, c*. Three independent closure phase relations from the March 1975 observations. The solid lines are predicted phases from the brightness distribution shown in Fig. 4 *a*.

resolve the usual 180° ambiguity in the position angle of the source, but it does not allow us to locate the absolute position of the radio source on the sky⁸. Apart from the absolute position of the source, we have derived all the complex visibility information accessible to these interferometers. In other words, the data can be regarded as synthesis observations of 3C147 with (u, v) coverage limited to the three US baselines.

The measured fringe amplitudes and the constructed phases were convolved on to a regular grid in (u, v) space using a Gaussian convolution function. Zero values were assigned to grid points not filled by this procedure. This array was then transformed into the sky plane resulting in the so-called 'dirty map' of the source, which is badly disturbed by sidelobes resulting from the incomplete u, v coverage. The effect of these sidelobes was reduced by means of a version of the CLEAN technique developed by D. Rogstad. The primary output of this program is an array of point sources in the sky plane which approximates the true source brightness distribution. This first 'map' can be improved slightly because of the small extent to which the extended structure does influence the observed fringe amplitude on baselines 4, 5, and 6. The corresponding phases can therefore be expected to show minor deviations from the assumed value of zero. To take account of this, the major features of the first 'map' were used to re-predict the phases on the long baselines and the analysis was repeated to produce a second 'map'. This process was continued and, while no significant changes were noted after the second or third iteration, five iterations were performed to check the stability of the derived brightness distribution.

The array of point sources produced by CLEAN has been smoothed with a Gaussian 'clean beam' whose FWHM is the same as that of the central maximum of the dirty beam. Fig. 4*a* shows the final composite clean map, the result of the fifth iteration, in which the clean beam is circular and has a FWHM of $0.009''$. In Fig. 3*a-c* the solid lines are the amplitudes and closure phases obtained by Fourier inversion of the final array of point sources only. The agreement with the data indicates that we have subtracted most of the real features of the dirty map.

We have also checked the sensitivity of this process to our original supposition of zero phases on the longer baselines. To do this, we repeated the above procedure exactly, except that initially we used phases predicted by the model of the source

shown in Fig. 2*b*. The result is shown in Fig. 4*b*; the brightness distributions in Fig. 4 are very similar and this gives us confidence that they accurately represent the compact features in the source.

The similarity between the brightness distributions shown in Figs 2*b* and 4, obtained from independent data by entirely different methods, is remarkable. The distribution of Fig. 2*b* predicts amplitudes lower and more smoothly varying than those actually observed on baselines 4, 5 and 6, indicating that the true distribution contains more compact features than those of the Gaussian model. Nevertheless, the agreement supports the conclusion of Pauliny-Toth *et al.*¹⁵ that the main features of a complex brightness distribution can usually be reconstructed reliably even without phase data. The objective nature of our method, however, the speed with which a complicated brightness distribution can be determined, and the avoidance of the 180° position angle ambiguity make this approach a significant advance on conventional model-fitting methods.

As well as the compact structure discussed above, 3C147 also has an extended component which has been observed both at low frequencies, by interplanetary scintillation observations^{6,16}, and at 2,695 MHz by single baseline, conventional interferometric observations⁴. At low frequencies ($\lesssim 100$ MHz) the extended component dominates, and $\gtrsim 80\%$ of the radiation must come from a region $\sim 0.7''$ in extent. At the higher frequency the compact features dominate, and only $\sim 25\%$ of the radiation originates in the extended region. In November 1976, 3C147 was observed twice with the Cambridge 5 km telescope at 15 GHz (M. Ryle, personal communication), and these observations show that the source is 30% resolved in p.a. $30^\circ \pm 5^\circ$ on the longest baselines, indicating a size $\sim 0.7''$. The source is unresolved in p.a. $\sim 120^\circ$. The position angle and the size are consistent with the model-fitting results of Donaldson and Smith⁴, and in Fig. 5 we show schematically a composite of our VLBI results with their preferred interpretation. The exact details of the extended structure are not known, but it is clear that the components are not colinear, and it seems that the outer lobe does not form a smooth extension of the jet. Note however, that only one contour of a Gaussian is drawn to indicate this outer lobe and it would not be surprising if future observations, with baselines of a few hundred thousand to about one million wavelengths, do

Table 2

Component	S_{peak} (Jy)	ν_{peak} (MHz)	θ_{eq} (arc s)	θ_{obs} (arc s)	Total energy (erg)	Pressure (dyn cm ⁻²)
Outer lobe	70 ± 10	120 ± 30	$0''.35$	$\sim 0''.6 \times 0''.15$	5×10^{57}	$\sim 10^{-8}$
Jet	20 ± 8	420 ± 100	$0''.05$	$\sim 0''.2 \times 0''.025$	5×10^{56}	$\gtrsim 3 \times 10^{-7}$
Core	3.2 ± 0.5	$500 \pm 200?$	$0''.012$	$0''.006$		
*Core (if on straight part of spectrum)	3.2	609	$\gtrsim 0''.0055$	$\sim 0''.006$		

* See text.

in fact show a bridge of emission between the jet and outer lobe. In this case the source would resemble 3C66B (ref. 17). The minimum resolution of our observations ($\sim 2 \text{ M}\lambda$) is too great to study the outer lobes, although they are probably the cause of the systematic deviations of the expected fringe amplitudes from the data on the shortest (OVRO-Ft Davis) baseline. The flux density of these lobes must be relatively greater at 609 MHz than at 2,695 MHz because the compact features shown in Figs 2b and 4 only account for about half the total flux density of 35 Jy from the source at 609 MHz.

The radio spectrum of 3C147

The total spectrum of 3C147 has a maximum at $140 \pm 20 \text{ MHz}$, and a marked low frequency cutoff, which is thought to be due

to synchrotron self absorption¹⁸. We have constructed three-point spectra for the individual components using the total spectrum and high resolution observations at 609 MHz (present data), 1,660 MHz (refs 5, 19), and 2,695 MHz. The 2,695 MHz points are taken from a re-analysis⁵ of the data of Donaldson and Smith⁴. In all cases, except 609 MHz, the core was taken to be unresolved ($\lesssim 0.01''$).

The spectra of the individual components cannot be determined with great accuracy; however, it is clear from the total spectrum that the spectra of both the outer lobe and the jet must have low frequency cut-offs. We have fitted to the data a series of three-component spectra, which are consistent with the total spectrum (Fig. 5). The parameters of the different components derived from these spectra are shown in the first two columns of Table 2.

The spectrum of the core is the least well determined of the three components. There is no indication of a low frequency cutoff and it is not possible to infer, even approximately, the frequency at which this occurs. The value of ν_{peak} in Table 2 of $500 \pm 200 \text{ MHz}$ has therefore been included merely as an indication of what might be reasonable (see later).

The energy balance in the different components

We now discuss the possible physical conditions which obtain in the different components.

The jet and outer lobe. A number of different mechanisms could be responsible for the low frequency cut-offs which we observe in the jet and outer lobes of 3C147. Of these, synchrotron self-absorption seems to be by far the most likely explanation since both free-free absorption and the Tsytovich-Razin effect would require too much thermal plasma in the components (~ 2 and $\sim 3,000 \text{ electrons cm}^{-3}$ respectively). If there were such a high density of thermal plasma present, it would cause considerably more depolarisation within the source than is observed²⁰. Scott and Readhead¹⁸ have recently shown that the turnover in the total spectrum is almost certainly due to synchrotron self-absorption (their work is based on low frequency measurements and therefore refers to the outer lobe), because the measured diameter at 81.5 MHz is within a factor 1.5 of the equipartition diameter, θ_{eq} , assuming that synchrotron self-absorption is responsible for the low frequency cut-off. Following the treatment of Scott and Readhead for a simple slab source we have calculated θ_{eq} for the three components of 3C147, and these are given in Table 2. It is clear that the observed angular sizes of both jet and outer lobe are consistent with equipartition.

The total energies and the pressures in the outer lobe and jet, calculated assuming equipartition between the particle and magnetic field energy densities are also shown in Table 2.

The compact core. The spectrum of the core is apparently flat (spectral index $\gtrsim 0.2$) down to $\sim 600 \text{ MHz}$. Since the cut-off has not been observed, we calculate a firm lower limit to θ_{eq} by assuming that the $S \propto \nu^{5/2}$ line of the self-absorbed spectrum passes through the 609 MHz point (see Table 2). The observations are only just consistent with equipartition ($\theta_{\text{eq}} \gtrsim 0.0055''$) if the core is a single homogeneous source. If the cut-off in the spectrum occurs at a frequency substantially lower than 609 MHz then there must be considerably more energy in

the particles than in the magnetic field. A flat spectrum can also be produced by several individually self-absorbed components whose spectra peak at different frequencies. The characteristic undulations can easily be missed if the individual flux density measurements are not determined to sufficiently high accuracy. Preuss *et al.*²¹ have recently detected at least two weak (maximum correlated flux density ≈ 0.26 Jy) components in 3C147 at 5,000 MHz with a baseline of $\sim 10^8$ wavelengths. Their

Fig. 5 Total source and individual component spectra. Errors of $\pm 20\%$ have been assigned to the component flux densities to take account of model fitting uncertainties. (See text for references.) (Inset: composite brightness distribution showing schematically the relationship between our results and the preferred interpretation of Donaldson and Smith⁴ at 2,695 MHz. much greater resolution and lack of knowledge of the location of these components makes it difficult to compare these results with ours. The characteristic size they derive, however ($0.004''$, that is, ≈ 30 pc) suggests that the results refer to the core and that our measured size may not refer to a single component.

Discussion

The observations and analysis described above constitute the most reliable determination of radio structure on the scale $0.01''$ to $0.25''$ for any source. The 'core', 'jet' and 'outer lobes' morphology is very similar to 3C66 (ref. 17), M87 (ref. 22) and 3C219 (ref. 23), and suggests that in trying to explain 3C147 one should concentrate on theories involving the generation of energy in a central highly active region, and the transfer of the energy to outlying regions via a collimated beam of waves and/or particles²⁴.

The angular extent of the jet ($\sim 0.20''$) corresponds to a projected physical length of ~ 1.5 kpc at the distance of 3C147. This is similar to the projected length of the M87 jet. Another similarity is that the 3C147 jet also contains discrete 'knots'. The two knots in 3C147 have linear diameters ~ 150 pc, somewhat larger than the radio knots in M87 (~ 50 pc) (ref. 25). Turland²³ has shown that there is a wide range in both the luminosity and size of radio jets. Our results on 3C147 are remarkable if the same physical processes are responsible for producing all jets, since the radio luminosity of the 3C147 jet is four orders of magnitude greater than that of the M87 jet, and yet the physical sizes of both jet and knots are very similar in the two cases. The difficulties associated with the confinement of the knots in M87 have been discussed by Okoye²⁶ and by Turland²³, who suggested that the optical extent of the knots is determined by the lifetime (~ 20 yr) of the electrons responsible for the optical emission assuming it to be synchrotron radiation.

The possibility, however, that these knots are confined should be seriously considered for the following reasons. Wilkinson²⁵ has shown that the sizes of the radio and optical knots in M87 are very similar, yet the radio emitting electrons have a lifetime $\gtrsim 10^3$ years, much greater than the light travel time across a knot. Similarly in 3C147, the synchrotron lifetime of the radio-emitting electrons ($\gtrsim 3 \times 10^3$ yr) is much greater than the light travel time across a knot, and therefore they must be confined. The pressure in the 3C147 knots is, however, at least an order of magnitude greater than in the optical knots of M87, and therefore it should be easier to confine the M87 knots than those in 3C147.

Our knowledge of the outer lobes is very limited but we do know that the overall position angle is different from the jet. Further VLBI observations with resolutions in the range $0.1''$ – $2.0''$ could determine the structure on this scale if the closure phase were used. The uncertainty about the exact locations of the lobes illustrates one limitation of the 'closure phase' technique—namely that we cannot use it to determine absolute positions. If we knew the position of the core it would be a simple matter to subtract the core and jet from the 15-GHz map of the source made with the 5-km telescope, and this would then show clearly the disposition of the more extended features.

We have shown that it is possible to use VLBI observations to make a reliable determination of the structure of compact features in a fairly complex source. To determine that structure on other scales we have also made three station observations at 327 MHz and 5 station observations at 1,667 MHz (in preparation). These should enable us to determine both the structure on a scale $\sim 0.002''$ to $\sim 0.5''$ and the spectra of the different components, since the inclusion of the closure phase information allows us to study the components at different frequencies without ambiguity. Thus these observations should provide us, for the first time, with a complete picture of the structure of a high redshift radio source on a scale of parsecs to kiloparsecs.

We thank Professor M. H. Cohen for useful discussions and support. We also thank Dr D. Rogstad for his help in using the CLEAN procedure, and H. Yee for computing assistance. We are grateful to the staff of each observatory for their help in making these observations, and we thank Professor Sir Martin Ryle for allowing us the use of 5-km telescope data before publication. A.C.S.R. gratefully acknowledges the support of the Royal Society Weir Research Fellowship. The Owens Valley Radio Observatory is supported by NSF grant AST 73-74660. The National Radio Astronomy Observatory is operated by Associated Universities Inc., under contract with NSF.

Secular changes in marine inundation of USSR and North America through the Phanerozoic

A. Hallam

Department of Geological Sciences, University of Birmingham, P.O. Box 363, Birmingham, UK

Analysis of palaeogeographic and facies maps of the USSR and North America confirms an overall trend towards marine regression through the Phanerozoic with a major deviation in the late Mesozoic. These are related to world-wide changes of sea level attributable primarily to a combination of continental thickening controlled by subduction processes, and changes in the overall length and hence volume of the oceanic ridge system.

AN apparent secular withdrawal of the sea from the continents during the course of the Phanerozoic, superimposed on shorter-term oscillations of sea level, has been inferred from world palaeogeographic maps^{1,2} and held to support the notion of slow earth expansion of $\sim 0.5 \text{ mm yr}^{-1}$ during that time³⁻⁶. This interpretation has been challenged by Armstrong⁷ and Hallam⁸, who argue that the secular withdrawal can be adequately explained without invoking a change in the Earth's radius, and by Wise⁹, who disputes the very fact of secular change. The problem is re-examined here using the analysis of palaeogeographic and facies maps of the USSR and North America, which leads to a discussion on the relative merits of the various hypotheses that can be put forward to account for Phanerozoic sea-level changes. Attention is devoted to the longer-term secular changes rather than the shorter-term transgressions and regressions.

Soviet Union

The series of palaeogeographic and facies maps of the Soviet Union published in the 1960s¹⁰, as yet unmatched for any other extensive region, allow a detailed analysis of changes in the areal extent of sea through the whole Phanerozoic by a technique outlined elsewhere¹¹. All palaeogeographic maps involve, of course, a degree of inference, but there can be little doubt from the abundant data provided that the Russian maps give a close approximation to the area of continent flooded at several intervals for each successive geological period, although areas of present continental shelf cannot be included because of lack of data.

As shown in Fig. 1, the sea spread slowly in the early part of the Palaeozoic to cover approximately 60% of the

USSR by middle Ordovician times. Thereafter there was a faster withdrawal to reach a minimum value at the Silurian-Devonian boundary, followed by a relatively rapid restoration to middle Ordovician values in the late Devonian and early Carboniferous. Subsequently a progressive withdrawal culminated in a minimum at the Permian-Triassic boundary. During the Mesozoic, there were two transgressive peaks, in the late Jurassic and late Cretaceous, interrupted by an early Cretaceous minimum and followed by a sharp Cainozoic decline interrupted by a small peak in the middle to late Eocene, and a further, more dubious, peak in the Pliocene. None of the Mesozoic and Cainozoic peaks attained the values of the Palaeozoic maxima and in fact barely extended beyond the Silurian-Devonian trough.

The close spacing of data points, back at least to the Devonian, rules out a systematic temporal bias, with the length of time intervals chosen increasing the probability of overestimating the extent of sea the earlier the period⁹. Indeed, the probability of losing the stratigraphic record through subsequent deep burial, metamorphism and erosion must increase with time, and so the maps for older periods are more likely to underestimate than overestimate the former extent of marine cover. Furthermore, cratonic areas such as the Russian Platform and margins of the Siberian Shield, in fact almost everywhere outside eugeo-synclinal regions, contain much more substantial proportions of carbonates and evaporites to terrigenous clastics in the Palaeozoic than Mesozoic or Cainozoic, implying more areally restricted and topographically subdued sediment sources (mechanical denudation rates on the present continents show a tendency towards an exponential increase with increasing topographic elevation¹²). Hence the Russian data support strongly the notion of Phanerozoic secular withdrawal of sea.

North America

The only comprehensive series of palaeogeographic maps available for North America is that published in the atlas of Schuchert¹³, which was used by Wise⁹ to demonstrate a condition of essentially constant continental freeboard throughout the Phanerozoic, interrupted by short-term oscillations of sea level, 80% of which remained within about 60 m of a normal freeboard level $\sim 20 \text{ m}$ above the present level. These maps were drawn, however, several decades before the atlas was published, and therefore do not take

Fig. 1 Area of the Soviet Union covered by sea at different times during the Phanerozoic, expressed in both relative and absolute terms. Dating based on Geological Society of London Phanerozoic time scale. into account extensive modern discoveries of strata, especially in the Arctic. Moreover, Schuchert left large areas of the cordilleran region blank for the Palaeozoic, but facies changes from areas further east clearly indicate a marine eugeosynclinal regime¹⁴. As with the USSR, Palaeozoic rocks of the North American central craton are much richer in carbonates than younger rocks, and testify to a correspondingly greater spread of sea, so that Schuchert's maps, based on erosional remnants, tend to be cautious and substantial underestimates for times earlier than the Mesozoic.

Data from a new atlas of facies distribution through time¹⁵ are here used to propose a revised graphical interpretation of North American data. In the absence of up-to-date palaeogeographic maps for individual stages, an attempt was made to determine the approximate maximum extent of sea for each period, using references cited in the atlas and making fairly conservative inferences. This allows a general comparison with Schuchert's data and the world data of the Termiers and Strakhov, plotted in a similar way (Fig. 2).

Schuchert considerably underestimated the former extent of seas from the Cambrian to the Lower Carboniferous. Subsequently, the Schuchert and revised North American curves match quite closely with only a relatively slight but systematic increase in inferred extent of flooding in the revised version. The revised curve matches the similarly plotted Russian curve much more closely than the Schuchert curve. The main differences are that the North American seas attained their maximum in the late Ordovician rather than the middle Ordovician and late Devonian-early Carboniferous, although the values are remarkably similar at around 60%, and the late Jurassic transgression was less extensive than the late Cretaceous. Because the two continents comprise approximately one-third of the Earth's land surface it might reasonably be inferred that the changes in question are primarily expressions of eustatic changes in sea level, with the relatively minor differences being attributable to regional differences in topography and rates of subsidence. This is confirmed by the close match of the two curves with those based on the Termier and Strakhov world palaeogeographic maps. A eustatic interpretation is both simpler and more plausible than the alternative proposed by Sloss and Speed¹⁶, that the continents have moved up and down in concert. An additional point is that the Permo-Triassic minimum must be due to a genuine eustatic fall and not to the silting up of shallow sea during a phase of stillstand. This is because the extent of end Permian and beginning Triassic non-marine sediments is negligible in both the USSR (Fig. 1) and North America.

Discussion

Several different explanations can account for the long-term secular changes under consideration. Earth expansion: besides the fact that the notion of slow earth expansion poses serious physical problems¹⁷ it has already been pointed out that the Phanerozoic overall regression can be explained more conservatively without considering a change in the earth's radius. In addition, the regression ought to have continued back into the Proterozoic, but the end of the Proterozoic was in fact a regressive phase. Thus Lower Cambrian deposits transgress widely on to much older rocks, often Archaean or early Proterozoic in age, a fact that has given rise to the term Lipalian interval. This regressive interval is probably comparable in magnitude with the end-Palaeozoic and late Cainozoic examples.

The alternative expansion model, which involves a much more rapid increase in the earth's radius since the early Mesozoic, leading to dispersal of the fragments of Pangaea^{6,18}, is even more clearly refuted by physical arguments¹⁹⁻²¹ and is incompatible with the dominantly

transgressive character of Mesozoic seas. Holmes⁴ even interpreted the Quaternary secular fall in sea level, superimposed on glacially-controlled oscillations, as a consequence of rapid earth expansion.

Glacial control: the onset of the Cainozoic ice age might be considered to have been responsible for a substantial component of the contemporary drop in sea level. It has been estimated that sea level would rise 46 m if all polar ice was melted⁷. An Antarctic ice sheet first formed in the late Miocene, although ice apparently started to accumulate as early as the late Eocene²². Abstraction of ice from the ocean system can only account for a small proportion of the lowering of sea level since the late Cretaceous high stand, however, if we accept the figure of slightly over 500 m computed from estimated changes through time of oceanic ridge volume²³, and supported independently by an estimate of the overall continental margin sedimentary overlap through the Cainozoic (P. R. Vail, personal communication).

The glacial explanation is even less successful in accounting for the major late Permian-early Triassic regression, which took place after the melting of the extensive late Carboniferous-early Permian Gondwana ice cap and the concomitant establishment of a more equable world climate.

Orogeny: plate tectonics provides a ready mechanism for the thickening and hence uplift of elongate sectors of crust at continental margins overlying subduction zones, by frictional melting of the descending slab giving rise to ascending magmas⁸, and perhaps more locally by the underthrusting of one continental edge beneath another. Thus closure of the Iapetus Ocean at the end of the Lower Palaeozoic in north-west Europe and eastern North America has converted a marginal basin-island arc-trench regime to a tectonically more stable zone of continent which has not been the site of subsequent orogeny but has persisted in most places as a positive area welded to the adjacent Precambrian shields and only locally and occasionally inundated by shallow sea.

With the detailed Russian data of Fig. 1, the clearest indication of orogeny correlating with regression concerns the substantial post-Valanginian eastward withdrawal of the sea in eastern Siberia, which is bound up with the younger Cimmerian Orogeny²⁴. The subsequent Aptian to Campanian transgression never reached as far west as the late Jurassic seas, and the Cimmerian event is the principal reason for the Russian late Cretaceous extent of sea being less than the late Jurassic, hence contradicting the world picture.

Similarly, the late Carboniferous-Permian regression is associated with the multiphase Hercynian Orogeny, commencing in the middle Carboniferous and reaching a climax in the early Permian, and converting the old Uralian and Angara geosynclines into cratonic regimes. More tentatively, the regression commencing in the late Ordovician and reaching a maximum at the end of the Silurian seems to be connected with the Russian equivalent of the Caledonian Orogeny, as manifested around the western and southern margins of the Siberian Shield. In the far east of the country, a notable end-Cretaceous orogeny is reported locally²⁴, and a number of minor Tertiary orogenic phases in the same region might help to account for part of the Cainozoic overall regression.

The North American data of Fig. 2 are, of course, less precise, but it is apparent that a component of the post-middle Ordovician Palaeozoic regression may be attributed to the progressive conversion of the Appalachian and neighbouring regions by the successive Taconic, Acadian and Appalachian orogenies from a geosynclinal-island arc zone into a positive upland area welded to the central North American craton, which lay beyond the reach of subsequent Mesozoic and Cainozoic transgressions. Like-

Fig. 2 Maximum degree of marine inundation for each geological period for USSR and North America (according to Schuchert and as revised in this paper, and comparison with the world data of Strakhov (a) and the Termiers (b), derived from ref. 8.

wise, the pronounced post-Cretaceous regression correlates with the Laramide Orogeny in the west of the continent.

That orogeny cannot account for all the regression is shown by examination of the history of extensive shield and platform areas of both continental masses, which were unaffected by Phanerozoic diastrophism. Thus the Russian Platform was extensively covered by shallow sea throughout the great bulk of Phanerozoic time but was completely emergent by the end of the Permian. A post-Cretaceous emergence is also apparent after the extensive late Mesozoic transgressions. Similarly, the Siberian Shield was substantially transgressed in the Cambro-Ordovician but a major withdrawal of the sea commenced in the west towards the close of the Silurian, with a land area emerging between the Ural and east Siberian seas. From middle Jurassic times onwards the sea covered the huge West Siberian depression but withdrew definitively in the Oligocene.

In North America, shallow seas covered a large part of the Canadian Shield from the Ordovician to the Devonian, but withdrew definitively in the Lower Carboniferous, as they did in the American mid-west in the Upper Carboniferous and Permian, and in the USA and Canadian Western Interior after the Cretaceous.

More generally, only a small percentage of the present land surface is occupied by 'Alpine' orogenic zones, yet it has been estimated that continental relief has increased by a factor of about 2.5 in the late Cainozoic²⁵.

Continental underplating: to account for the apparent emergence through the Phanerozoic of such cratonic areas

I formerly argued for a slight thickening by sialic underplating, using a term proposed for the African cratons by Shackleton²⁶. Several lines of evidence suggest, however, that old cratons have remained tectonically inert after the early Proterozoic and have been subjected to relatively little uplift or erosion since their time of formation, an interpretation supported by low heat flow at present²⁷. Persistence of ancient structural patterns and distinctive types of mineral assemblage is also incompatible with significant change at the base of the crust²⁸. Underplating, in fact, invokes a petrological process not required by plate tectonics and not supported by independent evidence. It is probably only relevant, if at all, to the Archaean.

Variations in rate of seafloor spreading: Hays and Pitman²³ attribute the late Cretaceous major transgression to a rapid seafloor spreading in the Pacific and Atlantic from 110 to 85 Myr, with a correspondingly greater extent of 'hot', buoyant oceanic ridge displacing seawater on to the continents. This interpretation relies on the accuracy of correlation of magnetic anomalies and has been questioned by Berggren *et al.*³⁰, who proposed an amended time scale consistent with more-or-less uniform rate of spreading. Even disregarding this criticism, the Hays and Pitman interpretation does not account satisfactorily for the marked secular regression through the Cainozoic. According to the data presented by Larsen and Pitman²⁹, the spreading rate for the Atlantic remained more or less constant from Palaeocene time onwards, and matched that for the late Jurassic and early Cretaceous. The rate was similarly con-

stant for the Phoenix-Pacific plate boundary, while the fuller data for the Farallon-Pacific plate boundary shows a fall at 85 Myr to a lower rate from the Coniacian to the Palaeocene. Thereafter there was a sharp but small reduction at the Palaeocene-Eocene boundary, a rise to a maximum in the Oligocene and subsequently a stepwise decline to the present. The Oligocene, however, is clearly regressive with respect to the Palaeocene and Eocene³¹.

Taking Indian Ocean data into account only complicates the picture further, and in a way not obviously consistent with the Hays and Pitman interpretation³². India moved away from Antarctica at a very rapid rate in the early Tertiary, and was followed by a period when little or no spreading took place west of the 90°E Ridge. Spreading from the Carlsberg Ridge has proceeded at a more or less constant rate of 1.2–1.3 cm yr⁻¹ over the past 30–35 Myr, back into the Oligocene, following a period of very slow spreading back to the late Palaeocene. In the central Indian Ocean the spreading rate has not been constant as in the Atlantic and Pacific, but changed from 5.7 cm yr⁻¹ in the Campanian to ~9 cm yr⁻¹, persisted at that rate until the middle Palaeocene and then decelerated.

Changes in length of ocean ridge system: the most plausible alternative to the spreading rate interpretation to account for the spectacular late Cretaceous transgression, which was obviously a very unusual geological event, is that a large volume of seawater was displaced by creation of new oceanic ridges in the South Atlantic and Indian oceans, since this was the time when effective dispersal of the fragments of Gondwana commenced. Such an interpretation would imply that the Cretaceous regression was due at least partly to the progressive loss of ridges elsewhere by subduction. That this is likely to have happened is evident from the analysis of Larsen and Pitman²⁹. According to their interpretation, in the middle Cretaceous there were four major plates in the Pacific region, the Kula, Farallon, Phoenix and Pacific plates. In the past 110 Myr there has been progressive consumption through subduction beneath Asia and the Americas of ridges separating the Kula from the Farallon, and the Farallon from the Phoenix plate, together with the Pacific-Kula ridge.

On the other hand, the early Tertiary saw the creation of new ridges between Greenland and Scandinavia as the North Atlantic opened, and between Antarctica and Australia. This might account for the worldwide Eocene transgression³¹ shown for the USSR in Fig. 1, which is against the secular Cretaceous trend.

Assessment of the role of ridges in pre-Cretaceous times must be highly speculative because the marine record is lost, but it seems possible that the more or less progressive Jurassic transgression relates in part to the creation of a ridge within the newly-opened central Atlantic, while the striking late Palaeozoic regression could to some extent be due to the consumption of spreading sea floor including ridges that had previously driven continents together to effect the Hercynian Orogeny.

The dominant cause of the longer-term Phanerozoic changes in sea level and overall regression is likely to have been a combination of continental thickening by orogeny consequent on subduction or collision, and variation in the cumulative length of the oceanic ridge system. The best prospect for testing these ideas quantitatively is in the Cretaceous, which has by far the fullest record of geological events per unit of time, both on the continents and ocean floor.

Location and bond type of intermolecular contacts in the polymerisation of haemoglobin S

Ruth E. Benesch, Suzanna Kwong, Reinhold Benesch & Rohinton Edalji

Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York, New York 10032

The solubility of 14 hybrid haemoglobins composed of α chains with a single substitution and β chains from HbS was compared with that of sickle haemoglobin. A substantial reduction in the insolubility of native deoxyhaemoglobin S results from surface mutations in certain regions of the α chain while changes in other areas have no effect. Also, the chemical nature of the substitution is decisive and points to the type of intermolecular bonding at several loci.

WE described previously the preparation of five haemoglobin double mutants carrying the $\beta 6$ Glu \rightarrow Val mutation as well as an additional one on the α chains^{1,2}. They were used to delineate regions on the surface of the molecule where significant bonding between neighbouring tetramers takes place in the polymerisation of deoxyhaemoglobin S. This work has now been extended to include portions of the α chain which were previously unexplored. In addition, the availability of more than one mutation at the same locus has now made it possible to infer the type of bonding involved in some of these intermolecular contacts.

Table 1 Mutant haemoglobins used for preparation of HbS hybrids

No.	Mutant Hb	Locus on α chain	Substitution	Ref.	Method of isolation*	
					α Mutant	Hybrid
1	Sawara	6	Asp→Ala	6	6	1
2	Anantharaj	11	Lys→Glu	7	4	2
3	HbI	16	Lys→Glu	8	3	5
4	Sealy (Hasharon)	47	Asp→His	9,10	2	1
5	Mugino (Kokura)	47	Asp→Gly	11	1	1
6	Montgomery	48	Leu→Arg	12	1	1
7	Shimonoseki	54	Gln→Arg	13	2	1
8	J Mexico	54	Gln→Glu	14	4	2
9	G Phila	68	Asn→Lys	15	—	1
10	Ube II	68	Asn→Asp	16	4	2
11	Mahidol	74	Asp→His	17	6	1
12	Winnipeg	75	Asp→Tyr	18	6	1
13	Q Iran	75	Asp→His	19	6	1
14	O Indonesia	116	Glu→Lys	20	2	1

*Conditions for isolation of α mutant and hybrid haemoglobin were as follows: 1, Chromatography on DEAE-Sephadex A-50 and elution with a 24-h linear gradient of 0.05 M Tris-HCl, pH 8.4→7.4. 2, As(1), but pH 8.0→7.4. 3, As(1) but 12-h gradient pH 8.0→7.0. 4, As(1) but 16-h gradient pH 7.7→7.0. 5, As(1) but pH 7.6→6.8. 6, Polyacrylamide gel electrophoresis²¹.

Preparation and characterisation of double mutant haemoglobins

Two different hybridisation reactions were used to prepare double mutant tetramers. The first^{1,2} is based on the exchange reaction

This method is suitable for separating the double mutant except where the mutation on the α chain brings about a change in charge which is equal and opposite to that of the β^S mutation, as for example in HbJ Mexico ($\alpha^{54\text{Gln} \rightarrow \text{Glu}}$). In such a case, the hybrid, $\alpha_2^X\beta_2^S$, will, of course, have the same charge as HbA and can therefore not be separated from it. This difficulty can be overcome by hybridisation of such α mutants with β_4^S since HbA is not a product of this reaction

Method (2) was therefore used in all cases where the effective charge of the double mutant was too near to that of HbA to permit a good separation. This was often encountered in haemoglobins where the formal difference in charge brought about by the mutation was modified by interactions with other residues.

HbS was isolated from the blood of heterozygous donors by chromatography on DEAE-Sephadex³ using a 24-h linear gradient of 0.05 M Tris buffer pH 8.0–7.4.

Hb β_4^S was prepared by treatment of the unfractionated A/S haemolysate with *p*-mercuribenzoate followed by chromatography on CM-cellulose as described by Bucci and Fronticelli⁴. The β^{SHg} fraction was collected, concentrated by ultrafiltration using PM 30 Amicon membranes and the mercury was removed with *N*-acetylpenicillamine as described previously⁵.

The α mutant haemoglobins including the five which were hybridised with HbS before^{1,2}, are listed in Table 1. Only mutants were chosen with substitutions at or near the surface of the molecule. The exact position of each residue was located on a three-dimensional model assembled from Labquip components using the refined coordinates of human deoxyhaemoglobin²². The haemoglobin variants were isolated from the blood of heterozygous donors. The samples were transported in temperature controlled containers (Trans-Temp 313, Fisher Scientific). The purity of the mutant haemoglobins was checked by polyacrylamide gel electrophoresis.

Hybrid tetramers with two β^S chains and α chains from mutants 3, 4, 5, 6, 7, 9 and 14 (Table 1) were prepared by method (1) as described previously^{1,2}. The remainder were made by method (2) using β_4^S as donor of β^S chains. Equal amounts of 1% solutions of α mutant haemoglobin and β_4^S were mixed and incubated in 0.2 M

acetate buffer pH 4.7 for 3–4 h at 0 °C. The $\alpha_2^{\text{Shimo}}\beta_2^S$ hybrid was made by both methods and HbS was also prepared from β_4^S and HbA. The conditions for the isolation of the double mutant haemoglobins are given in Table 1. The identity and purity of the hybrids was established by polyacrylamide gel electrophoresis of the intact haemoglobins and, in some cases, of the mercurocurated subunits.

The oxygen equilibrium curves of all haemoglobins including the hybrids were measured as described before^{23,24} using 10 μ M haemoglobin in 0.05 M bis-Tris buffer pH 7.4 at 20 °C.

The structural and functional integrity of the hybrid tetramers was tested using the criteria applied previously^{1,2}. The oxygen affinities of all the double hybrids were the same as those of the α mutant from which they were derived and, with two exceptions, were within the normal range ($\log p_{50} = 0.43$ – 0.56 at 20 °C and pH 7.4). Hb Mugino and $\alpha_2^{\text{Mugino}}\beta_2^S$ had a somewhat raised oxygen affinity ($\log p_{50} = 0.36$) and Hb Sawara was found to be a really high affinity mutant ($\log p_{50} = 0.02$), contrary to a previous report¹¹. In this case too, the Sawara-S hybrid retained the high affinity.

The oxygenation properties of HbS prepared from HbA and β_4^S by method (2) were identical with those of native HbS ($\log p_{50} = 0.47$).

Solubility in strong phosphate as measure of HbS polymerisation

The solubility in concentrated phosphate buffer, as originally described by Itano²⁵, was chosen for comparing the polymerising tendency of the double mutants with that of HbS, since only small quantities of the double mutants were available (15–30 mg). Several lines of evidence support the assumption that this method measures the same phenomenon as the usual gelling tests on much larger samples: (1) While the precipitation of oxy and deoxyhaemoglobin A as well as that of oxyhaemoglobin S is essentially instantaneous when they are mixed with the phosphate buffer, deoxyhaemoglobin S precipitates slowly, which presumably reflects the time required for the formation of ordered polymers. The suspensions were therefore incubated with gentle shaking for at least 30 min at 25 °C and the filtrates were observed for further precipitation. Incomplete precipitation introduces increasingly large errors as the fraction of haemoglobin in solution decreases with increasing ionic strength. (2) Cottam and Waterman²⁶ concluded from the parallel temperature dependence of the solubility and the gelation that the former constitutes 'a sensitive method of monitoring the aggregation phenomenon of deoxyhaemoglobin S'. (3) Both with some chemically modified HbS molecules²⁷ and in the case of two naturally occurring double mutants, the results obtained by the two methods were similar. Thus HbC Harlem was 2.5 times more soluble than HbS in strong phosphate²⁸ and its minimum gelling concentration was 36 g % instead of 24.5 g % for HbS (ref. 28). Hassan *et al.*²⁹ have shown

Table 2 Solubility of deoxygenated double mutants

Haemoglobin	α -chain locus	Solubility (mol l ⁻¹ × 10 ⁵)
$\alpha_2^A\beta_2^S$	—	0.3
$\alpha_2^{\text{Winnipeg}}\beta_2^S$	75	0.2
$\alpha_2^{\text{Sawara}}\beta_2^S$	6	0.2
$\alpha_2^{\text{Q Iran}}\beta_2^S$	75	0.3
$\alpha_2^{\text{Mahidol}}\beta_2^S$	74	0.3
$\alpha_2^{\text{Ube II}}\beta_2^S$	16	0.9
$\alpha_2^{\text{Mugino}}\beta_2^S$	68	0.9
$\alpha_2^{\text{G Phila}}\beta_2^S$	47	0.9
$\alpha_2^{\text{Anantharaj}}\beta_2^S$	68	1.1
$\alpha_2^{\text{Montgomery}}\beta_2^S$	11	1.5
$\alpha_2^{\text{J Mexico}}\beta_2^S$	48	1.5
$\alpha_2^{\text{Shimo}}\beta_2^S$	54	1.7
$\alpha_2^{\text{O Indonesia}}\beta_2^S$	54	1.8
$\alpha_2^{\text{Sealy}}\beta_2^S$	116	2.0
	47	4.6

The measurements were carried out as described previously³⁰ in 2.04 M phosphate buffer pH 6.8 ($\mu = 4.4$) at 25 °C. The values were obtained by interpolation or extrapolation of solubility plots such as those shown in Fig. 1.

that the double mutant, Hb Stanleyville II/S ($\alpha_2^{78 \text{ Lys}}\beta_2^{6 \text{ Val}}$) is twice as soluble in strong phosphate as native HbS and this is paralleled by an increase in the minimum gelling concentration from 24 to 30 g %.

Effect of α -chain mutations on the solubility of HbS

The solubility of the deoxy form of all the double mutants used in 4.4 ionic strength phosphate buffer is given in Table 2. Clearly, the effect of the mutations varies over a wide range from no effect at all at positions 6, 74 and 75 to the 20-fold increase in solubility caused by the replacement of aspartic acid by histidine at position 47.

Another criterion was also used to compare the various double mutants with HbS—the change in ionic strength ($\Delta\mu$) necessary to make the solubility of the oxy and deoxy form equal in each case (Fig. 1). This value was 1.35 for HbS and 0.22 for HbA.

The effect of a mutation in the α chain on the solubility of the tetramer it forms with β^S chains depends not only on the location of the substitution but also on its chemical nature.

The most instructive from this point of view were the three pairs of mutants at positions $\alpha 47$, $\alpha 54$ and $\alpha 68$. The results obtained on the hybrids of these mutants with HbS are shown in Table 3. The

Fig. 1 Solubility of haemoglobins A (a) and S (b) in phosphate buffer pH 6.8 at 25 °C. Open symbols, oxyhaemoglobin; filled symbols, deoxyhaemoglobin.

**Table 3** Effect of α -chain mutations on solubility of HbS

Haemoglobin	Position on α chain	Residue	$\Delta\mu^*$
$\alpha_2^A\beta_2^S$	47 (CD6)	Asp	1.35
$\alpha_2^{\text{Mugino}}\beta_2^S$		Gly	1.07
$\alpha_2^{\text{Sealy}}\beta_2^S$		His	0.58
$\alpha_2^A\beta_2^S$	54 (E3)	Gln	1.35
$\alpha_2^{\text{Shimo}}\beta_2^S$		Arg	0.78
$\alpha_2^{\text{J Mexico}}\beta_2^S$		Glu	0.78
$\alpha_2^A\beta_2^S$	68 (E17)	Asn	1.35
$\alpha_2^{\text{G Phila}}\beta_2^S$		Lys	1.08
$\alpha_2^{\text{Ube II}}\beta_2^S$		Asp	1.10

*Change in ionic strength necessary to make the deoxy and oxy forms equally soluble.

greatest solubilising effect on deoxyhaemoglobin S encountered among 14 different substitutions on the α chain is that due to replacement of aspartic acid by histidine at $\alpha 47$ (Hb Sealy). But, when the substitution at this locus is glycine, as in Hb Mugino, the solubilising influence is greatly reduced (Table 3). We therefore conclude that the aspartate side chain at $\alpha 47$ is engaged in an intermolecular salt bridge which materially contributes to the stability of the helical polymer. Wishner *et al.*³¹ and Edelstein *et al.*³² also concluded that $\alpha 47$ is in an important contact region. If the spacial relations in the fibre can be assumed to be similar to the arrangement of the double strands seen in crystals of deoxyhaemoglobin S the most likely partner for aspartate $\alpha 47$ is lysine $\beta 59$ on the adjacent molecule³¹.

Table 3 shows that the glutamine residue at $\alpha 54$ also provides an important intermolecular contact point. Here, however, the same increase in solubility is observed whether the glutamine is replaced by a positive residue (Hb Shimonoseki) or a negative residue (HbJ Mexico). Although the solubility data show that $\alpha 68$ is a weaker contact point altogether, the nature of the bond must be of the same kind as that at $\alpha 54$, since here again, both a negative and a positive substitution have the same effect. This evidence suggests apolar bonds at these two locations. Hydrophobic bonding is generally assumed to be important in the polymerisation of HbS as, for example, indicated by the temperature dependence of the gel formation³³. In this connection it is pertinent to recall a parallel situation involving the β chains where no gelation occurs when the valine at $\beta 6$ is replaced either by glutamic acid (HbA) or by lysine (HbC).

A second region of the tetramer surface formed by the α chains qualifies as a weaker contact area. It contains residues $\alpha 11$, $\alpha 16$ and $\alpha 116$, brought into proximity by the tertiary structure of the protein. The mutations at these loci (Hb Anantharaj, HbI and HbO Indonesia) all have comparable effects on the solubility of HbS (Table 4).

A particularly significant group of mutants were Hb Sawara ($\alpha 6$), Hb Mahidol ($\alpha 74$) and haemoglobins Winnipeg and Q Iran ($\alpha 75$). In all these cases the hybrid composed of the abnormal α chains and β^S chains had the same solubility as HbS itself (Table 5). The three-dimensional model of the tetramer shows that these three loci ($\alpha 6$, $\alpha 74$ and $\alpha 75$) are situated quite close together with $\alpha 6$ being somewhat recessed from the surface. This part of the surface can therefore be designated as a non-contact region. It should be noted that two of these mutants—haemoglobins Mahidol and Q Iran—carry the same substitution (Asp→His) as does Hb Sealy

Table 4 Effect of α -chain mutations on solubility of HbS

Haemoglobin	Position on α chain	Substitution	$\Delta\mu^*$
S	—	—	1.35
$\alpha_2^{\text{Anantharaj}}\beta_2^S$	11 (A9)	Lys→Glu	0.86
$\alpha_2^{\text{I}}\beta_2^S$	16 (A14)	Lys→Glu	1.15
$\alpha_2^{\text{O Indonesia}}\beta_2^S$	116 (GH4)	Glu→Lys	0.84

*Change in ionic strength necessary to make the deoxy and oxy forms equally soluble.

Table 5 Effect of α -chain mutations on solubility of HbS

Haemoglobin	Position on α chain	Substitution	$\Delta\mu^*$
S	—	—	1.35
α_2 Sawara β_2^S	6 (A4)	Asp→Ala	1.37
α_2 Mahidol β_2^S	74 (EF3)	Asp→His	1.35
α_2 Winnipeg β_2^S	75 (EF4)	Asp→Tyr	1.33
α_2 Q Iran β_2^S	75 (EF4)	Asp→His	1.33

*Change in ionic strength necessary to make the deoxy and oxy forms equally soluble.

($\alpha 47$). As the same change has a maximal effect at $\alpha 47$, but none at $\alpha 74$ and $\alpha 75$, the location on the surface of the molecule is clearly the decisive factor.

The Hb Sawara hybrid also shows that a high oxygen affinity is not incompatible with efficient polymerisation of deoxyhaemoglobin S. The same situation was encountered previously with HbS from which the α C-terminal residue had been removed—desArg HbS (ref. 1).

This method of approach has thus made it possible to define several distinct areas on the surface of the haemoglobin molecule formed by the α chains. One of these is a region of strong intermolecular bonding which includes aspartate $\alpha 47$, leucine $\alpha 48$ and glutamine $\alpha 54$. Of these, $\alpha 47$ aspartate probably forms a salt link with lysine $\beta 59$ on the next molecule while glutamine $\alpha 54$ participates in hydrophobic bonding.

A region where replacement of the normal residues has a smaller effect in solubilising HbS is enclosed by the charged residues at $\alpha 11$, $\alpha 16$ and $\alpha 116$. All three are therefore candidates for electrostatic bonding. Another contact point of comparable significance is the asparagine at $\alpha 68$, engaged in hydrophobic bonding. A weak effect brought about by a single substitution could be the result of multiple contacts in that region so that replacement of only one of them would weaken the contact by only a fractional amount.

Finally, the mutations at $\alpha 6$, $\alpha 74$ and $\alpha 75$ provide an excellent control, since changes at these positions—and in the case of $\alpha 75$ even two different substitutions—have no effect whatever on the solubility of native HbS.

In Fig. 2, the 10 different loci with one or more substitutions, which were included in this study are marked on a schematic representation of the haemoglobin tetramer. But, the distance between the different positions can only be judged from the three-dimensional model and not from this necessarily two-dimensional substitute.

We thank Drs S. Pootrakul, S. Rahbar, D. Labie, J. Rosa, J. Alperin, M. Grey, R. Rieder, T. Hosty, P. Galbraith, T. Imamura and T. Miyaji for blood samples. This work was supported by US PHS grants HL-17552 and HL-05791 from the National Heart and

Synchronised transmembrane insertion and glycosylation of a nascent membrane protein

James E. Rothman & Harvey F. Lodish

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Studies of the synthesis and incorporation of the vesicular stomatitis virus glycoprotein into membranes in a synchronised cell-free system demonstrate a tight coupling between polypeptide synthesis and membrane insertion, as a result of which the nascent chain crosses the membrane. The studies reveal a surprisingly precise sequence by which the nascent chain of this membrane glycoprotein is glycosylated in two steps. These findings have important implications for the mechanisms of membrane assembly.

MEMBRANES are continuously formed and remodelled in all living cells, and the problem of how membranes are assembled is central to cell biology. But, the mechanisms by which proteins are incorporated into membranes and the means by which specific proteins are directed only to the appropriate membrane or organelle are obscure. We describe here a novel approach to these problems which has begun to elucidate the nature and temporal sequence of the events responsible for the synthesis and membrane insertion of ectoproteins¹, those integral membrane proteins which have a hydrophilic domain on the extra-cytoplasmic side of the membrane. The external portion(s) of

ectoproteins must somehow cross the permeability barrier of the membrane at some stage. Several considerations¹ suggest that the external portions of the polypeptide chain of an ectoprotein cross the membrane during protein synthesis, but direct evidence has been lacking. The alternative school of thought² holds that ectoproteins can be inserted into membranes after they are completely synthesised.

The glycoprotein (G) of vesicular stomatitis virus (VSV) is such an ectoprotein. Most of the protein of G and all of its carbohydrate are external to the lipid bilayer of the viral envelope, forming the 'spikes' which project radially from the surface of the viral particle³. The G protein is synthesised by ribosomes bound to the endoplasmic reticulum^{4,5} of infected cells and receives at least the core *N*-acetylglucosamine and mannose sugars in this organelle⁶⁻⁸. G is a transmembrane protein of the endoplasmic reticulum membrane, oriented with its sugar-containing portion within the lumen of the organelle, but with about 30 amino acids at its carboxy terminus exposed on the opposite, cytoplasmic side of the membrane^{8,9}. G is ultimately transported from the reticulum to the plasma membrane, during which time the glycosylation is completed by the addition of terminal sialic acid residues^{6,7}, and is subsequently incorporated into the viral envelope following the budding out of the viral nucleocapsid through the cell surface membrane³.

A cell-free system capable of supporting membrane assembly has been described⁹ in which the VSV G protein was translated from viral-specific mRNA in crude extracts of wheat germ. When G was synthesised in the presence of membrane vesicles derived from the rough endoplasmic reticulum of pancreas (but freed of endogenous ribosomes), this membrane protein was glycosylated and was asymmetrically inserted into the vesicle membrane, spanning the lipid bilayer, with the same orientation as the native G protein found in the rough endoplasmic reticulum *in vivo*.

We report here a simple method for synchronising the growth and processing of the G protein in this cell-free system. This technique has revealed a remarkably close degree of coupling between polypeptide synthesis and incorporation into the membrane, and has made it possible to demonstrate a precise sequence by which the nascent chain of the membrane protein is glycosylated.

Synchronisation of protein synthesis

Protein synthesis is started when total VSV mRNA is added to a cell-free extract of wheat germ. After 2 min of protein synthesis, a specific inhibitor of initiation¹⁰, 7-methylguanosine-5'-phosphate (⁷mGp) is added to prevent subsequent initiations. If this interval is sufficiently short in comparison with the time required to complete the G protein, and if all of the nascent glycoprotein chains grow at the same rate, then in principle, all copies of the G protein will be polymerised in synchrony as a cohort population.

Figure 1 shows that an approximation to synchrony can be obtained by this procedure. The synthesis of total VSV protein proceeds linearly for a limited period (Fig. 1a), beyond which no further protein is made, as would be expected if initiation were completely blocked by ⁷mGp. In the absence of ⁷mGp, synthesis is linear for about 60 min (not shown). No completed G protein can be observed until about 45 min, when all chains of G are observed to be completed within a rather brief time span of 10 min (Fig. 1b). Total protein synthesis is apparently complete before the appearance of G protein because G is a minor fraction of the total translation products and greatly exceeds most of the products in chain length.

Coupling of insertion and glycosylation to protein synthesis

To determine the degree to which the processes of insertion and glycosylation of G are coupled to protein synthesis, synthesis of G chains was initiated synchronously in the absence of pancreatic membrane vesicles, and at various times samples were removed and the chains were completed in the presence of vesicles. This

experiment determines the maximum size of nascent glycoprotein which can be made without any association with membranes without affecting proper insertion and glycosylation.

As shown previously⁹, the partially glycosylated form of the glycoprotein (G₁) migrates more slowly (see Fig. 2) through sodium dodecyl sulphate-polyacrylamide gels than does the unglycosylated form (G₀) which results from synthesis in the absence of pancreatic membrane vesicles. The extent of glycosylation was therefore determined as the fraction of G

Fig. 1 Synchronisation of protein synthesis. Wheat germ extract and VSV were prepared and proteins were synthesised at 23 °C, essentially as before⁹, in a volume (including all additions) of 0.5 ml containing 0.15 ml wheat germ extract, 20 μ l VSV mRNA, 27 mM HEPES (pH 7.2), 120 mM KCl, 1.5 mM magnesium acetate, 5.6 mM dithiothreitol, 2.6 mM ATP, 0.26 mM GTP, 16 mM creatine phosphate, 0.73 mM spermidine, 42 μ g ml⁻¹ creatine phosphokinase, 0.13 mM each of the 19 amino acids, except methionine, and ³⁵S-methionine (0.5 mCi ml⁻¹) with a specific radioactivity of approximately 600 Ci mmol⁻¹. The mixture was pre-incubated for 1.5 min at 23 °C before adding mRNA at time zero. After 2 min, 25 μ l of a 20 mM solution of ⁷mGp (P. L. Biochemicals) were added, giving a final concentration of 1 mM. *a*, At various times, duplicate samples of 2 μ l were taken, and the total protein synthesised was determined as radioactivity insoluble in boiling 5% trichloroacetic acid (TCA). The amount of acid-insoluble radioactivity at zero time (550 c.p.m.) was subtracted to yield the data in the figure. *b*, At various times, samples of 25 μ l were precipitated with TCA and separated by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate⁹. The amount of G protein present was determined from scans of autoradiographs of the dried gels. The triangles and circles represent data from two experiments, run in identical conditions. The amounts of G protein shown are values obtained by normalisation to the amount of G protein made at the longest time point shown for each experiment, in order to permit the two experiments to be compared directly. Note that the concentration of ⁷mGp required to achieve satisfactory inhibition of initiation (> 99%) is very sensitive to the KCl concentration and that the time for chain completion can vary markedly ($\pm 50\%$) between independently prepared extracts of wheat germ.

protein in the G_1 form. Trypsinisation of vesicles after protein synthesis removes peptides from the extreme C-terminal region of G_1 , yielding a large fragment which migrates slightly faster than G_1 (but more slowly than G_0) on acrylamide gels (Fig. 2) and is protected from further tryptic degradation by the permeability barrier of the membrane vesicle^{8,9} wall through which G_1 is inserted. G_0 yields no analogous protected portion⁹. The extent to which the G protein was properly inserted into the membrane was, therefore, assayed as the fraction of radioactivity in the total G product ($G_0 + G_1$) preserved in the membrane-protected tryptic fragment which runs between G_0 and G_1 on gels. Even if all copies of G were inserted correctly, some loss of radioactivity would be expected since three C-terminal peptides containing ³⁵S-methionine radioactivity are removed by trypsin in the process of conversion of G_1 to the protected fragment⁹.

Figure 2 shows that when chains are completed in the presence of membranes after 6 min of synchronous synthesis in the absence of membranes, the resulting G protein is all in the G_1 , or glycosylated form, and yields a membrane-protected fragment on trypsinisation. A dramatic change takes place thereafter. Few of the G chains made for 9 min in the absence of membranes, and then completed in the presence of membranes, are glycosylated, and little if any membrane-protected fragment is observed (Figs 2, 3). Both glycosylation and proper insertion are lost coordinately and remarkably rapidly after 6 min. Indeed, both processes are lost within a span of 3 min, when the window in which initiation was permitted was 2 min. Consequently, prolonging synthesis of a G chain (which was initiated at 0 min) in the absence of membranes beyond the critical time of about 6 min by as little as 1 min will result in a marked reduction of proper insertion and of glycosylation. A fourfold increase in the concentration of membranes does not cause a significant increase in the critical time of about 6 min (not shown), indicating that this time is not related to the rate at which ribosomes can

Fig. 2 Membrane addition experiment. At the indicated times, 50 μ l samples of the same protein synthesis incubation as Fig. 1 (Δ) were removed, 0.5 μ l of pancreatic microsomal membranes (prepared as before⁹; stock suspension had an A_{280} of 50, as measured in 1% sodium dodecyl sulphate) were added, and incubation was continued at 23 °C until 53 min had elapsed from the time mRNA was added. One half of each sample was precipitated with TCA⁹, while the other half was treated with trypsin-TPCK (0.5 mg ml⁻¹) at 23 °C for 15 min before TCA precipitation. Shown here is the autoradiogram of the gel of the translation products for the 6 and 9 min time points. Only the region of the gel containing G is presented; no time-dependent changes were observed for the other viral proteins. The gel was impregnated with scintillant³³ before drying, and the film was exposed for 40 d at -70 °C. The band below G_1 in the trypsin-treated lanes has methionine containing tryptic peptides of G (F. Katz, personal communication), and varies greatly in amount between experiments. Its significance is unclear.

Fig. 3 Effect of the time of membrane addition on glycosylation and proper insertion. Same experiment as Fig. 2. The autoradiogram of the gel was scanned, and the amounts of G_0 and G_1 (lanes without trypsin treatment) and of the large membrane-protected tryptic fragment of G_1 (lanes with trypsin treatment) were determined from the peak heights. The extent of glycosylation (●) is $G_1/(G_0 + G_1)$. The extent of protection of G by membranes (○) is the amount of fragment (running between G_0 and G_1) divided by $G_0 + G_1$ determined from the lane without trypsin of the same time point.

encounter membranes when the two are first mixed. This suggests that the critical time is dependent on some intrinsic property of the nascent G protein. This view is strongly supported by experiments in which the time for completion of G was about 23 min (using a different wheat germ preparation from Fig. 3), and the critical time for proper insertion was only 3 min. The critical time is therefore proportional to the time required for completion of the polypeptide.

If it is assumed that the growth of the G polypeptide is proportional to time, then the approximate length of the chain at the critical time can be determined. G has a molecular weight of ~63,000 (ref. 11) and therefore contains approximately 550 amino acid residues. In the experiment of Fig. 3, the chain was completed in 40 min, so about 80 residues would have been completed at the critical time. Of these, about 40 are present within the large subunit of the ribosome^{12,13}, so that only 40 residues would be available for any interaction with membrane vesicles. Synthesis of no more than 10–15 additional residues in the absence of membranes at this critical chain length results in the loss of proper insertion into the membrane and of glycosylation.

It can be concluded that both insertion into the membrane and glycosylation are closely coordinated with polypeptide chain synthesis, for membranes are required almost from the outset.

Sequence of glycosylation

The finding (Fig. 4) that protein synthesis in wheat germ extracts is unaffected by high concentrations of the detergent Triton X-100 has permitted the times of the glycosylation events to be determined in a simple experiment, and has led to the discovery of a novel intermediate in glycosylation. The lack of effect of Triton at concentrations as high as 1% (or possibly higher) is in marked contrast to the complete inhibition by the bile salt deoxycholate at much lower concentrations, as found for the reticulocyte system¹⁸. Concentrations of Triton as high as 1% would be expected to completely solubilise the pancreatic vesicle membranes, and might be expected to cause an abrupt inhibition of glycosylation by producing a random physical segregation of the nascent G chain (with attached ribosome), the glycosyltransferases, and the presumed lipid-linked sugar

Fig. 4 Effect of detergents on protein synthesis. Conditions of protein synthesis were essentially the same as Fig. 1, except no ³H-mGp was added. Shown is the amount of TCA-insoluble protein made in 60 min per 2 µl of reaction as a function of the concentration (w/v %) of either Triton X-100 (▲) or sodium deoxycholate (●).

substrates into different detergent micelles. Indeed, all of the G protein which results from translation of VSV mRNA in the presence of pancreatic membranes and 1% Triton X-100 is in the G₀ (unglycosylated) form (Fig. 5).

These results imply that the timing of glycosylation can be explored by synchronising protein synthesis with ³H-mGp as before but with the exception that membrane vesicles are present from the outset. At various times, samples are taken and Triton X-100 is added to inhibit further glycosylation, and the polypeptide chains are completed in the presence of the detergent. From the resulting distribution of G chains between glycosylated and unglycosylated forms as a function of the time of detergent addition, the times of glycosylation events can be inferred. Thus, when detergent is added before any glycosylation has taken place, no subsequent glycosylation can occur, so all of the resulting G will migrate in the G₀ position. When Triton is added after all glycosylation is completed, only the G₁ form will result.

Figure 5 shows that up to 9 min of synchronous synthesis, no glycosylation has taken place since only G₀ is observed. After 29 min, mainly G₁ is observed, so glycosylation is mainly complete well before the chain is finished. In between, and particularly around 20 min, a previously unknown form of G predominates, migrating on the gel in between G₀ and G₁. The amounts of these three forms as a function of the time of addition of detergent are shown in Fig. 6. The novel form of G, called G_{1/2}, is clearly a kinetic intermediate in the formation of G₁. This form binds specifically to columns of concanavalin A-Sepharose 4B, as judged by the methods used previously⁹ (data not shown), and is therefore (as expected from its intermediate mobility in gels) an intermediate in glycosylation.

The VSV virion glycoprotein contains two essentially identical oligosaccharide side chains¹⁴. As it is unlikely that both of the sites are glycosylated at the same time, and as the Asn-linked oligosaccharide would be derived by *en bloc* transfer from a lipid-linked oligosaccharide^{15,16}, an intermediate form in which one of the two sites is glycosylated would be expected. It was confirmed recently by analysis of the kinetics of degradation of G₁ by endoglycosidase H that G_{1/2} contains only one of the two oligosaccharides (J. Rothman, in preparation). This enzyme attacks each oligosaccharide at only one site, generating partial degradation products in proportion to the number of glycosylated Asn residues. It was found that G₁ was converted to G_{1/2}, which was then converted to G₀.

Since glycosylation is completed before the completion of the polypeptide backbone (Fig. 6), it is clear that the transfer of oligosaccharides is to the nascent chain. The rather precise kinetics of glycosylation probably indicate that each of the two

successive transfers of oligosaccharides to the nascent chain can only occur only after specific lengths of the nascent chain have been made because the timing of these events is determined only by the time required to complete G. When 23 min were required for completion of G chains (using a different wheat germ preparation from that used in Fig. 6), G_{1/2} was maximal at 12 min, and G₁ was half-maximal at 17 min, as compared with 22 min for G_{1/2} and about 30 min for G₁ when about 43 min were required for completion of G (Fig. 6).

Implications for the mechanism of insertion

Figure 7 presents a diagram of what is currently known of the sequence of events which occur during the synthesis of the VSV glycoprotein.

Our finding (Fig. 3) of a very early requirement for membranes implies that the insertion of G protein into the membrane has already begun when 80 or fewer residues are made, of which only 40 or fewer can be available for any interaction with membranes. The experiment only indicates the longest chain length which still permits subsequent insertion, so these figures place an upper limit on when insertion actually occurs. Glycosylation events are evidently not the basis for the early membrane requirement as both glycosylation steps occur well after the requirement for membranes is expressed (Fig. 7). Glycosylation is therefore not important for insertion of the membrane protein, at least in the initial stages. Presumably, insertion into the membrane proceeds continuously after it has begun.

In addition, our results strongly suggest that the nascent chain spans the lipid bilayer such that the protein is extruded across the membrane as it is being polymerised, as predicted from considerations of membrane asymmetry¹. This conclusion follows immediately from the fact that the chain is glycosylated while it is still attached (through tRNA) to the ribosome on the 'cytoplasmic' side of the membrane, providing it is assumed that the glycosylation steps take place on the opposite side of the membrane, within the vesicle.

Implications for the mechanisms of glycosylation

The belief that glycosylation is restricted to the extracytoplasmic surface of membranes is widespread and is based on the fact

Fig. 5 Triton X-100 addition experiment. Protein synthesis was performed in the same conditions as Fig. 1, except the final volume was 0.95 ml and pancreatic microsomal membranes (20 µl) were present before adding mRNA at time zero. At 2 min, 1 mM ³H-mGp was added. At each indicated time, a sample (25 µl) was removed, 2.5 µl of 10% (w/v) Triton X-100 was added, and incubation at 23 °C was continued until 53 min had elapsed from the time of addition of mRNA. Samples were then precipitated with TCA and electrophoresed as before⁹. Only the regions of the autoradiogram of the gel containing G are shown since no time-dependent changes in other viral proteins were observed. The gel was impregnated with scintillant³³ before drying, and was autoradiographed for 40 d at -70 °C. The band above G₁ was observed in the presence or absence of membranes, varied between experiments, and was not time-dependent. The G₁ chains required between 40 and 45 min for completion in the presence of membranes in this experiment, as determined by the methods of Fig. 1 (data not shown). The rate of elongation of proteins is therefore unaffected by the presence of membranes.

Fig. 6 Sequence of glycosylation. The amounts of G-specific translation products, G_0 , $G_{1/2}$ (the band between G_0 and G_1 in Fig. 5), and G_1 were determined for each time point from the peak heights of the corresponding bands in the acrylamide gel for the experiment which is partially presented in Fig. 5. The amount of each form is expressed as a % of the total of the three forms. G_0 (●), $G_{1/2}$ (●), G_1 (○). Arrow indicates polypeptide chain completion.

that membrane carbohydrate is found only on that side^{1,2}. Consistent with this, we have found (Fig. 3) that both glycosylation and proper insertion of the VSV glycoprotein are lost coordinately when membrane vesicles are added too late, in spite of the fact that the glycosylation steps themselves do not take place until well after this requirement for membranes is expressed (Fig. 7). This indicates that the late glycosylation depends on the early insertion of the nascent chain into the membrane on the 'cytoplasmic' side. This implies that the late glycosylation steps occur when the nascent chain of the G protein is present on the opposite, luminal side of the vesicle membrane.

We have presented here the first direct evidence that the nascent chain of a membrane glycoprotein is glycosylated. Kiely *et al.*¹⁷ showed that the majority of the carbohydrate is attached only to those peptide chains of ovalbumin (a secreted protein) that have been essentially completed. The timing of the two glycosylation steps of the VSV glycoprotein (Fig. 6) is remarkably precise. Each glycosylation takes place only after a specific length of the polypeptide chain is made. One explanation for this would be that the order and timing of the glycosylations is determined only by the order of the two acceptor residues in the amino acid sequence, that is, when the acceptor Asn residues first appear on the luminal side of the membrane.

Fig. 7 Sequence of events during the synthesis of G protein. The numbers below the arrow indicate the fraction of the chain completed, assuming the chain grows at a constant rate. The time of the first glycosylation is when G_0 is half of its original value, and the time for the second glycosylation is when G_1 is half maximal (Fig. 6).

Another plausible explanation would be that only when specific lengths of chain are made (and perhaps only for small intervals of chain length) is the nascent membrane protein in the appropriate conformation to act as an acceptor. In this case, an Asn would not generally be glycosylated at a time which corresponds to its position in the amino acid sequence. Such a conformation would presumably require that the Asn acceptor site of the nascent chain be in intimate proximity with the luminal surface of the lipid bilayer, in order to permit enzymatic transfer from the dolichol-oligosaccharide donor, located at the same interface.

Role of signal sequences

The considerations discussed above and elsewhere^{4,19} imply that the ribosomes which manufacture G protein are bound to the membrane by the nascent chain, if by no other interaction. Our results show for the first time that membrane-bound ribosomes engaged in the secretory process can be derived from free ribosomes after initiation of protein synthesis, a central aspect of the 'signal hypothesis'^{20,21}. Thus, when G chains are started in the absence of membranes on free ribosomes, and then subsequent initiation is blocked, these same ribosomes must become bound to the membrane in a functional configuration in order to permit the insertion and glycosylation of the resulting G protein which is observed when membranes are added at sufficiently early times (Fig. 3). Earlier work²¹ did not distinguish whether initiation occurred on added free ribosomes before or after they became bound to the membrane.

It then follows that these free ribosomes must possess a 'signal' which directs them to the correct membrane to bind in a functional way, permitting the nascent chain to be extruded through the membrane, as proposed in the 'signal hypothesis'^{20,21}. This signal could, in principle, be found in sequences of mRNA or of the nascent polypeptide itself. Support for the localisation of the 'signal sequence'²¹ to the N terminus of the nascent chain has come from the original finding of a precursor to the immunoglobulin light chain containing an additional sequence at the N terminus²⁰ and the subsequent finding that a wide spectrum of proteins secreted by pancreas possess essentially identical N-terminal extensions which are removed from the proteins in the endoplasmic reticulum²². Much additional work has shown that, quite generally, secreted proteins²³⁻³¹ (as well as a membrane ectoprotein³²) have similar N-terminal extensions some 15-30 residues in length. Unfortunately, direct evidence for the function of these extensions as the proposed signal sequences has been lacking.

Our findings now provide direct evidence for an N-terminal signal sequence which functions in the predicted manner²¹. Thus, the requirement for membranes during synthesis of G protein is not expressed until some 40 residues are found outside the ribosome, a length of chain just sufficient to contain any of the N-terminal extensions cited above. On the basis of the signal hypothesis, membranes could not be required until all of the signal sequence is translated and outside the large ribosomal subunit. The rapid loss of proper insertion of G when no more than 10-15 additional residues are made would then indicate that the signal sequence contained within the N-terminal 40 residues can only function during a short interval in the synthesis of the glycoprotein. There is as yet no evidence for a significant cleavage at the N terminus of G, but there is no obvious reason why an N-terminal signal sequence need be cleaved off.

The mechanisms used by the VSV glycoprotein to enter membranes can be expected to be relevant to most or all cellular ectoproteins since the limited coding capacity of the viral genome (five proteins, all structural components of the virion) requires that it utilises cellular factors for glycoprotein glycosylation and insertion. Indeed, the diverse sources of the components (plant ribosomes and animal membranes) which function together in the cell-free system indicate a high degree of evolutionary conservation of the mechanisms involved. The results obtained do not reflect unique properties of the particular

components used since the glycoprotein produced in the cell-free system is indistinguishable from the glycoprotein found in the endoplasmic reticulum of infected cells⁹. Further investigations using the cell-free system may provide more detailed insights into the mechanism by which the nascent chain crosses the membrane, and the relationship of signal sequences to this mechanism.

Radio haloes around BL Lacertae objects AO0235+164 and 4C03.59

THE rapid variations in intensity and linear polarisation of several BL Lacertae sources at centimetre and optical wavelengths have indicated the presence of multiple non-thermal components, often appreciably smaller than 1 pc (refs 1, 2). But there is no clear evidence for radio structures extended over kiloparsecs around any of the known variable BL Lac sources which have been scanned with narrow beams of a few arcs³⁻⁷. The absence of extended radio structure in brighter and more variable BL Lac sources has also been inferred from their flat or inverted radio spectra and has led to the suggestion that these are extremely 'young' QSOs which have yet to develop a steady, non-thermal background⁸⁻¹⁰. We report here the lunar occultation and interplanetary scintillation (IPS) observations of two BL Lac sources, AO0235+164 and 4C03.59 at 327 MHz. One of the two occultations of the former source, which is known to be an exceptionally violent variable at centimetre, infrared and optical wavelengths, took place in November 1975 near the epoch of its major outburst¹¹⁻¹³. These observations indicate that at 327 MHz, part of the emission of both these sources originates in components larger than 1 arc s.

The Arecibo occultation source AO0235+164 was identified with a 19-mag stellar object and was shown to be a radio and optical variable having an inverted radio spectrum and a featureless, steep optical spectrum^{3,16,17}. During late 1975, when this BL Lac source flared up dramatically, spectrometry revealed two optical absorption-line systems^{14,15} at redshifts of $z=0.524$ and 0.852 and also HI absorption¹⁵ at $z=0.524$. The strikingly rapid flux variations of this source impose extreme constraints on the incoherent synchrotron interpretation for rapidly varying extragalactic sources, if their redshifts are cosmological^{12,13,18}. The other BL Lac source 4C03.59 also has a steep optical spectrum^{3,19,20} but only a normal, straight radio spectrum²¹ with a slope of -0.6 and has been classified as a possible radio variable²². Visual images of both these BL Lac objects exhibit a jet-like nebulousity extending up to ~ 3 arc s from the stellar nucleus^{13,17,20}.

The lunar occultation and IPS observations at 327 MHz were made using the Ooty radio telescope. The methods of reducing such observations are described elsewhere²³⁻²⁵. The results are given in Table 1, Figs 1 and 2. Occultation scans were observed for three position angles across AO0235+164 on 28 August and 18 November, 1975 and for four position angles across 4C03.59 between December 1973 and October 1974. The IPS observations were reduced using PKS1148-00 as calibrator, for which observations at Ooty have shown that its scintillation index rises to a maximum value of $85 \pm 5\%$ (S. Ananthakrishnan, personal communication).

After applying corrections for beam-broadening to the restored strip scans of Fig. 1, we estimate the half-power width of an equivalent gaussian source to AO0235+164 to be 3.0 ± 1.4 , 6.3 ± 1.8 and 3.7 ± 1.5 arc s in position angles of 21° , 66° and 140° , respectively. Thus AO0235+164 is resolved significantly at 327 MHz. We have also carried out IPS observations of this source on 10 days during April and May 1977, which indicate a scintillating component of size < 0.1 arc s containing a flux of 0.75 ± 0.15 Jy out of the total 1.07 ± 0.11 Jy at 327 MHz (Table 1). A simple interpretation of these measurements would be that at 327 MHz

Size of the IPS component	<0.1 arc s	0.25 \pm 0.05 arc s

* The flux scale is as defined by Veron, Veron and Witzel²⁶.

[†] The values inside brackets are the centroid positions measured at 2.7 GHz using the RRE interferometer^{16,22} and are in excellent agreement with the positions of the identified optical objects, measured on the Sky Survey prints to an accuracy of ± 0.4 arc s in each coordinate^{16,27}.

Fig. 1 The strip-brightness distributions across AO0235+164 are shown for the three indicated position angles. The resolutions are indicated by bars. Right ascension increases to the left. The scan in position angle 66° was observed on 18 November 1975 near the peak of the major radio outburst of this source^{11,12}.

the source consists of a core of size <0.1 arc s which accounts for nearly two-thirds of the total emission and an underlying extended component having a size of a few arc s. During VLBI observations²⁸, carried out in 1970 with a fringe spacing of 0.05 arc s, the source showed a maximum amplitude of 0.97 ± 0.27 Jy at 430 MHz, as compared with the total flux of 1.50 ± 0.16 Jy measured by Sutton *et al.* at 408 MHz²⁹. These two measurements indicate that either the entire flux is contained in a gaussian source of size ~ 0.02 arc s which was only partially resolved by the VLBI or, alternatively, that the measured visibility was due to an unresolved core of size <0.01 arc s and the remainder flux comes from a broad component. The latter interpretation would be consistent with the simple model suggested above.

After correcting the strip scans shown in Fig. 2 for beam-broadening, the half-power width of the source, 4C03.59(2335+031), is estimated to be 1.5 ± 0.5 arc s. The source profile in position angle 109° shows a faint but probably real extension towards east. This could be identified with the optical nebulosity of a few arc s which is seen extending from the stellar object identified with this source²⁰. In addition to the above structure, there is also

Fig. 2 Strip-brightness distributions across 4C03.59 are shown for the four indicated position angles. The resolutions are indicated by bars. Right ascension increases to the left.

evidence for a more compact, scintillating core contributing $10 \pm 5\%$ of the total flux at 327 MHz (Table 1).

The extended radio features of size ≥ 1 arc s detected in these two BL Lac sources have brightness temperatures exceeding $\sim 10^9$ K at 327 MHz. Hence their emission at metre wavelengths is likely to be predominantly non-thermal. Assuming that the absorption-line redshift $z=0.852$ for AO0235+164 represents its cosmological redshift and for Einstein-de Sitter model with $H=50$ km s⁻¹ Mpc⁻¹, the extended component of this source has a size of ~ 50 kpc and a minimum energy density of $\sim 10^{-10}$ erg cm⁻³ in the form of relativistic electrons and magnetic field.

Like many QSOs, the BL Lac source AO0235+164 exhibits multiple absorption systems¹⁴. The absorption could arise either in the intervening galaxies along the line of sight or within gas clouds located near its nucleus and being driven away due to its large radiation pressure^{30,31}. An important requirement in the latter model is that the gas clouds do not expand freely during their outflow, though the mechanism of their confinement is not clear³²⁻³⁴. The confinement may occur due to external pressure caused by the extended non-thermal component, provided the simple core-halo model of the source is valid. But, the present observations are also consistent with a more complex structure without a halo. It may also be noted that the mildly relativistic speeds of the outflowing absorbing clouds, as are inferred³⁵ from the multiple-redshift systems in QSOs and AO0235+164, are attainable only in a period of $\geq 10^5$ yr after the ejection³². It is interesting that a similar age of $\geq 10^5$ yr is also implied for AO0235+164 by the measured size of its extended component, taking this non-thermal component to be an expanded remnant of the past activity in its nucleus.

I thank Professor G. Swarup and Dr M. N. Joshi for their valuable comments.

A constraint on the universal baryon density from the abundance of ${}^7\text{Li}$

THE observed interstellar abundance of ${}^2\text{H}$ has been used^{1,2} to estimate the mean baryon density (ρ_b) of the Universe. This follows, because (1) there is no plausible source for ${}^2\text{H}$ other than the primordial big bang and (2) the production of ${}^2\text{H}$ in a standard big bang decreases rapidly with increasing ρ_b . If one then assumes that all ${}^2\text{H}$ was formed in a big bang, the observed abundance² of this nuclide requires a value of ρ_b sufficiently low¹ that, for a cosmological constant $\Lambda=0$, the present expansion of the Universe will continue forever and the Universe is open. A major weakness in this argument is that another source of ${}^2\text{H}$ may be found. It has been suggested, for example, that ${}^2\text{H}$ could be made in shock waves accompanying a supernova explosion; this now seems unlikely⁴, but other mechanisms will certainly be suggested, so that it is important to obtain confirmation of the above conclusion. The predicted production of ${}^7\text{Li}$ in a big bang² varies rapidly with ρ_b and could be used to estimate ρ_b if the fraction of the observed ${}^7\text{Li}$ made in the big bang were known. Unfortunately there are many possible sources⁴ of ${}^7\text{Li}$ and such estimates must be regarded with scepticism. In this note we point out that ${}^7\text{Li}$ can be used to place an upper limit on ρ_b , even if other production mechanisms are important, and that this limit also strongly favours an open universe. This possibility arises because the big bang production of ${}^7\text{Li}$ increases with increasing ρ_b (for

$\rho_b > 10^{-31}$) so that an upper limit is obtained by attributing all of the observed ${}^7\text{Li}$ to the big bang.

We have adopted here Boesgaard's⁵ value of the Li abundance which yields⁶ a fractional abundance by mass of ${}^7\text{Li}$, $X_7 = 5 \times 10^{-9}$. Assuming the big bang must not synthesise more than this amount leads to $\rho_b \leq 1.1 \times 10^{-30} \text{ g cm}^{-3}$. As is shown in Fig. 1, this is substantially less than the critical value ρ_c necessary to close a $\Lambda=0$ Friedman universe.

The uncertainty in X_7 is perhaps a factor of two; the meteoritic value⁶, for example, is $X_7 = 8 \times 10^{-9}$. Substantially larger values have been seen⁵ in a small number of red giant stars, but these values presumably reflect a local production mechanism. Allowing for a factor of two uncertainty gives an upper limit closer to ρ_c , but still favouring an open and forever expanding universe.

The existence of mechanisms which destroy ${}^7\text{Li}$ weakens the limit on ρ_b since the big bang may then have made more ${}^7\text{Li}$ than is now observed; conversely, discovery of additional sources of ${}^7\text{Li}$ strengthens the limit. Astration of primordial material is presumably the most important destruction process. Estimates of the fraction of matter which has passed through stars are rather uncertain but are typically about 0.5. It has been pointed out^{4,7}, however, that infall of primordial material from the galactic halo may be significant and would tend to compensate for the effects of astration for those nuclei produced in the big bang. Other sources of ${}^7\text{Li}$ are generally rather speculative⁴, except for production in the cosmic rays which yields roughly 10% of the observed ${}^7\text{Li}$. Since these various effects tend to offset each other, the observed value of X_7 seems reasonable but subject to uncertainty.

If it is a good approximation to ignore both astration and sources of ${}^2\text{H}$ and ${}^7\text{Li}$ other than the big bang, their observed abundances each separately determine the density. An estimate based on the ${}^2\text{H}$ abundance X_D is shown in Fig. 1, and is in good agreement with the density obtained from ${}^7\text{Li}$. Effects of astration would tend to worsen this agreement. Thus when other possible contributions to ${}^7\text{Li}$ are better understood, the requirement that the big-bang contribution to X_7 and X_D yield the same value of ρ_b may be a strong constraint on allowable astration.

We assumed above that the cosmological constant $\Lambda=0$. While this is consistent with the available data, a non-zero value cannot be excluded, except on aesthetic grounds, and its effects must be considered. It has been found¹¹ that for reasonable values of Λ , the limits on ρ_b from the ${}^2\text{H}$ and ${}^7\text{Li}$ abundances are essentially unchanged. But, the simplest relationship between ρ_b and the curvature and evolution of the Universe is no longer valid¹¹.

In summary, the simplest and most straightforward assumptions concerning the origin of ${}^7\text{Li}$ and the nature of the big bang expansion require an upper limit for the present universal density of $\rho_b = (1.1 [+1.1 \text{ or } -0.4]) \times 10^{-30} \text{ g cm}^{-3}$. Given that the Universe is indeed a Friedman universe with zero cosmological constant, the agreement between the present limit and that based on ${}^2\text{H}$ strongly supports the conclusion of Gott *et al.*¹ that the Universe is open and will continue to expand forever.

This research was supported by the USNSF.

Note added in proof: It has come to our attention that conclusions similar to those reached here have been discussed by G. Steigman at the Harvard Neighborhood Meeting on Cosmology, October 1975.

Fig. 1 Abundances of ${}^2\text{H}$ and ${}^7\text{Li}$ produced in a standard big bang (adapted from ref. 8). The present black body temperature is taken to be 2.90 K, see ref. 9.) The vertical line labelled ρ_c (55) is the density necessary to close a Friedman universe with $\Lambda=0$, if $H_0 = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (in general $\rho_c = 5.7 \times 10^{-30} (H_0/55)^2$). The point labelled X_7 is the mass fraction of ${}^7\text{Li}$ corresponding to the abundance given by Boesgaard⁵, while that labelled X_D is the mass fraction of ${}^2\text{H}$ from the summary of ref. 2. (This latter value is smaller than that used by Gott *et al.*¹, mostly because they include an estimate of the effects of astration). The uncertainty indicated for X_7 is a factor of two in either direction while that for X_D covers the range from a factor of four smaller to a factor of two larger¹⁰. Corresponding values of ρ_b and their uncertainties are also shown. The value of ρ_b determined from the ${}^7\text{Li}$ abundance is only an upper limit if there are significant sources of ${}^7\text{Li}$ other than the big bang.

Quantitative analysis of the Dermott-Gold theory for Uranus's rings

DERMOTT and Gold¹ have attempted to explain the locations of Uranus's rings in terms of resonances between ring particles and pairs of satellites, such that each particle librates about consecutive conjunctions of the satellites. The libration argument is given by

$$K = \lambda_1 - (p+1)\lambda_2 + p\lambda_3$$

where $\lambda_i = n_i t + \text{constant}$, $i = 1, 2, 3$, are the mean longitudes of the ring particle and the satellites, and p is an integer. Despite the apparent success of the theory in predicting the main observed features of the rings, it is necessary to investigate the strength of the resonances in more detail before any conclusions can be drawn. This letter summarises the outcome of such an investigation which supplements the previous largely qualitative analysis¹.

Aided by a study by Wilkens² of possible three-body resonances involving one minor and two major planets, I derived an equation of motion analogous to that of a pendulum

$$\frac{d^2 K}{dt^2} = c \cdot \sin K$$

where c is found to be roughly proportional to $m_2 m_3 (a_2/a_3)^p$, that is the product of the masses of the two satellites times the ratio of their semi-major axes to the p -th power. In Table 1, the first column gives the mass products adopted by Dermott and Gold for various pairs of satellites. The second column contains the range of values for $p = (n_1 - n_2)/(n_2 - n_3)$ required to span the observed width of the ring system—roughly 45,000–52,000 km. The corresponding range of c -values and of libration periods ($P = 2\pi c^{-1/2}$) are given in the final two columns (the quoted periods are for zero-amplitude librations; the period increases slowly with the amplitude, being twice as large for 164° as for 0°). Since $c > 0$, librations can occur only about $K = 180^\circ$.

On the basis of the magnitudes of the product $m_2 m_3$ and the resulting ring pattern, Dermott and Gold concluded that the observed pattern is probably due primarily to the Ariel-Titania and Ariel-Oberon pairs. From the values of c , however, we now see that the correction factor $(a_2/a_3)^p$ makes Miranda play the key role rather than Ariel, in spite of the small mass of the former. Furthermore, the single combination Miranda-Ariel dominates over all the others in terms of efficiency and predicts ring radii for $p = 7, 8$ and 9 which are very close to the radii obtained by Marsden³ for the ϵ_2 , γ , and α rings, respectively. Therefore, when applied to this and other satellite pairs, the Dermott-Gold mechanism, as modified here, seems to have the capability of explaining the observed ring locations. It is not clear, though, how much statistical weight this argument should be given, one problem being that the model may predict too many rings—which, incidentally, provides hope for a future observational test. The relatively low p values of the pairs involving Miranda may also add some new credibility to the theory. It is interesting to speculate that even lower values for p —and higher ones for c —would be attainable for a hypothetical pair of satellites involving Miranda and an as yet undiscovered satellite inside it. After all, the 80,000-km wide gap between the rings and Miranda is not likely to be entirely empty.

On the other hand, the very long libration periods derived in Table 1, when compared with revolution periods of only about a third of a day for the ring particles, put very tight constraints on the semi-major axes of librating particles. A radial displacement of the order of $\Delta a_1 = a_1 \sqrt{c/n_1} \leq 50$ m is enough to disrupt the extremely weak particle-satellite-satellite coupling

—and there are several competing forces that might set up a disturbance of that magnitude. Elliot *et al.*⁴ have estimated ring widths of from 12 to 85 km and particle sizes < 6 km. The theory cannot account for these observations unless the particles are assumed to have slightly eccentric orbits. One important question not yet answered is whether the restoring force of the particle 'pendulum' is sufficiently strong to overcome the Poynting-Robertson effect for reasonable particle sizes.

Table 1 Ranges of p , c , and $P = 2\pi c^{-1/2}$

Satellites	$m_2 m_3 \times 10^{11}$	p	$c(1,000 \text{ yr})^{-2}$	$P(1,000 \text{ yr})$
Miranda, Ariel	19	7–9	53–18	0.87–1.5
Miranda, Umbriel	5	4–6	5.0–1.1	2.8–5.9
Miranda, Titania	32	3–5	6.9–0.69	2.4–7.5
Miranda, Oberon	25	3–4	1.8–0.32	4.7–11
Ariel, Umbriel	99	15–20	4.6–0.73	2.9–7.4
Ariel, Titania	580	8–11	2.1–0.15	4.4–16
Ariel, Oberon	447	7–10	0.32–0.01	11–62
Umbriel, Titania	170	20–26	$(88–3.7)10^{-4}$	67–320
Umbriel, Oberon	131	15–19	$(63–2.1)10^{-5}$	$(2.5–14)10^3$
Titania, Oberon	770	66–83	$(56–0.32)10^{-8}$	$(0.84–11)10^4$

In conclusion, although sceptical of the Dermott-Gold theory, despite its ingenuity and elegance, I believe that a decisive test of the theory has to await further observational details of Uranus's rings. In the meantime, it would seem advisable to look for alternative ring theories. For example, Colombo (personal communication) points out that it may be of significance that the period associated with the ϵ ring is in the approximate ratios 5:4, 6:5, 9:8, and 11:10 to those associated with the α , β , γ , and δ rings. One should not discount the possibility, either, that the rings may be transient features not locked into any kind of resonance at all.

Revenge of tiny Miranda

DERMOTT and Gold¹ have proposed a resonance model for the rings of Uranus. They assume the rings are, in fact, arcs composed of small particles librating about stable resonances determined by pairs of satellites, either Ariel and Titania or Ariel and Oberon. Dermott and Gold dismiss as insignificant resonances involving tiny Miranda. We report here that, by a wide margin, the strongest resonances are all associated with Miranda. Furthermore, we show that the hypothesis that the rings are made up of librating particles, while original and ingenious, is incorrect.

Before considering the quantitative analysis of the resonance model, we make two minor points. First, when allowance is made for the orbital motion (assumed prograde) of the ring material between occultations, it is found that the two occulting regions of each ring were physically only 35° (α ring) to 46° (ϵ ring) apart. Thus, only short arcs are required to fit the observations. Second, while large systematic errors may remain in the calculated absolute ring radii, the spacings between the rings are well determined and must be accurately predicted by a resonance theory. In Table 1, the spacings predicted by Dermott and Gold are compared with those deduced by Elliot *et al.*² and Marsden³. The discrepancies seem to be larger than observational error and exhibit no systematic trend.

We have calculated the strengths of the resonances between a ring particle in circular orbit and either a single satellite or a pair of

satellites. The resonance strength is expressed as the magnitude of the resonant term in the disturbing potential, R , felt by the ring particle. Figure 1 shows the strengths of the most important resonances in the radial range $42 \times 10^3 \text{ km} < a < 54 \times 10^3 \text{ km}$, which spans the ring radii. The only two-body resonances included in Fig. 1 are the 4:1 and 5:1 resonances with Miranda. Two-body resonances involving other satellites also lie in the range of the rings. The strengths, however, are too small for them to show in Fig. 1.

The strongest resonances are the two-body resonances with Miranda which occur where

$$4n_M - n - 3 \frac{d\tilde{\omega}_M}{dt} = 0$$

or

$$4n_M - n - \frac{d\tilde{\omega}_M}{dt} - \frac{d\Omega}{dt} - \frac{d\Omega_M}{dt} = 0$$

Here, n_M and n are the mean motions of Miranda and the ring particle, Ω_M and Ω are the longitudes of their ascending nodes, and $\tilde{\omega}_M$ is the longitude of Miranda's periape. The resonance strengths are given by Brouwer and Clemence⁵.

$$R_1^4 = \frac{GM m_M}{48a M} \frac{a}{a_M} e_M^3 \left[-256\alpha + \left(142 + 114\alpha \frac{d}{d\alpha} + 21\alpha^2 \frac{d^2}{d\alpha^2} + \alpha^3 \frac{d^3}{d\alpha^3} \right) b_{1/2}^{(1)}(\alpha) \right]$$

and

$$R_2^4 = \frac{GM m_M}{4a M} \frac{a}{a_M} e_M (\sin i/2)^2 \left[\left(8 + \alpha \frac{d}{d\alpha} \right) b_{3/2}^{(2)}(\alpha) \right]$$

where M is the mass of Uranus, m_M and e_M the mass and eccentricity of Miranda, i the mutual inclination of the ring and Miranda's orbit, and $\alpha \equiv a/a_M$.

The functions $b_s^{(i)}$ are Laplace coefficients.

There are three 5:1 resonances, corresponding to

$$5n_M - n - 4 \frac{d\tilde{\omega}_M}{dt} = 0$$

$$5n_M - n - 2 \frac{d\tilde{\omega}_M}{dt} - \frac{d\Omega}{dt} - \frac{d\Omega_M}{dt} = 0$$

and

$$5n_M - n - 2 \frac{d\Omega}{dt} - 2 \frac{d\Omega_M}{dt} = 0$$

Using formulae given by Peirce⁶, we obtain the resonance strengths:

$$R_1^5 = \frac{GM m_M}{384a M} \frac{a}{a_M} e_M^4 \left[-3125\alpha + \left(1569 + 1556\alpha \frac{d}{d\alpha} + 402\alpha^2 \frac{d^2}{d\alpha^2} + 36\alpha^3 \frac{d^3}{d\alpha^3} + \alpha^4 \frac{d^4}{d\alpha^4} \right) b_{1/2}^{(1)}(\alpha) \right]$$

$$R_2^5 = \frac{GM m_M}{16a M} \frac{a}{a_M} e_M^2 (\sin i/2)^2 \left[\left(85\alpha + 20\alpha^2 \frac{d}{d\alpha} + \alpha^3 \frac{d^2}{d\alpha^2} \right) b_{3/2}^{(2)}(\alpha) \right]$$

$$R_3^5 = \frac{3GM m_M}{8a M} \frac{a}{a_M} (\sin i/2)^4 \left[\alpha^2 b_{5/2}^{(3)}(\alpha) \right]$$

where a and α now refer to the position of the 5:1 resonance. All of these strengths depend sensitively on the uncertain values of e_M and i . Greenberg⁴ has determined that $e_M \approx 0.012$ and $i \approx 4^\circ$, though

he regards the latter as "extremely model dependent". Using these values, and noting, therefore, that only R_1^4 and R_1^5 are likely to be reasonably accurate, we obtain

$$R_1^4 \approx 6.6 \times 10^{-13} \frac{GM}{a}$$

$$R_2^4 \approx 1.1 \times 10^{-11} \frac{GM}{a}$$

$$R_1^5 \approx 9.1 \times 10^{-15} \frac{GM}{a} \quad (7)$$

$$R_2^5 \approx 3.0 \times 10^{-13} \frac{GM}{a}$$

and

$$R_3^5 \approx 5.2 \times 10^{-14} \frac{GM}{a}$$

Next, we consider three-body resonances of the form

$$qn - (p+q)n_B + pn_A = 0 \quad (8)$$

where p and q are integers and n the mean motions with the subscripts A and B denoting the outer and inner satellites respectively. Both satellite orbits are assumed to be circles and to be outside the rings. The dominant resonant term in the disturbing potential arises as follows. Outer satellite A perturbs the orbit of inner satellite B, producing oscillatory variations in its radius and longitude with frequencies $p(n_A - n_B)$. The potential at the ring due

Fig. 1 The strengths of two- and three-body resonances in the neighbourhood of Uranus's rings. \otimes , The 4:1 and 5:1 resonances with Miranda discussed in the text and identified by $e = e_M$ and $\sigma = \sin(i/2)$; \bullet , the three-body resonances for $q=1$ and values of p as indicated. The resonances previously¹ associated with the rings are shown as +.

to B moving on its perturbed orbit contains terms with frequencies $qn - (p + q)n_B + pn_A$. These include the resonant term and many short period terms. Additional, but smaller (by a factor $\lesssim 0.1$), resonant terms arise from the attraction of A moving on an orbit perturbed by B. Finally, there are much smaller resonant terms due to the interaction between the direct perturbations of the ring by each satellite moving on its unperturbed circular orbit. The dominant resonant term is easily shown to be

$$\begin{aligned} R_{pq} = & \frac{GM}{2a} \frac{m_A m_B}{M^2} \frac{a_A^2}{a_B^3} \frac{n_A^2}{[p^2(n_B - n_A)^2 - n_B^2]} \times \\ & \times \left\{ h_q(\alpha) \left[f_p(\beta) - \frac{2n_B}{p(n_B - n_A)} g_p(\beta) \right] + g_q(\alpha) \times \right. \\ & \times \left. \left[\left(1 + \frac{3n_B^2}{p^2(n_B - n_A)^2} \right) g_p(\beta) - \frac{2n_B}{p(n_B - n_A)} f_p(\beta) \right] \right\} \quad (9) \end{aligned}$$

where a is orbital radius, m the satellite mass and $\alpha \equiv a/a_B$, $\beta \equiv a_B/a_A$. The functions f_k , g_k and h_k may be expressed in terms of Laplace coefficients (ref. 5) $b_k^{(j)}$ by

$$f_k(x) = x b_{3/2}^{(k)}(x) - \frac{1}{2} [b_{3/2}^{(k+1)}(x) + b_{3/2}^{(k-1)}(x)] + \delta_{k1} \quad (10)$$

$$g_k(x) = \frac{1}{2} [b_{3/2}^{(k-1)}(x) - b_{3/2}^{(k+1)}(x)] - \delta_{k1} \quad (11)$$

$$h_k(x) = \frac{1}{2} [b_{3/2}^{(k-1)}(x) + b_{3/2}^{(k+1)}(x)] - b_{3/2}^{(k)}(x)/x + 2\delta_{k1} \quad (12)$$

We have calculated the strengths of all $q = 1$ resonances due to each pair of satellites using power series approximations for the Laplace coefficients and satellite parameters from Greenberg⁴. The results are displayed in Fig. 1, with a smooth curve connecting the resonances due to each satellite pair. It is apparent that resonances involving tiny Miranda, the innermost satellite, dominate the field. The Ariel-Titania and Ariel-Oberon resonances advocated by Dermott and Gold¹ are relatively weak and presumably incapable of determining the ring locations.

Figure 1 shows that the strong Miranda-Ariel resonances lie close to four of the rings: Millis *et al.*'s ring 5 (ref. 7) and Elliot *et al.*'s rings α , γ and ϵ_2 , (ref. 2). Differences between Marsden's³

Table 1 Observed compared with resonant ring spacings

calculated positions for these rings and the resonances corresponding to $p = 10, 9, 8$ and 7 are 155, 96, 157 and 111 km, respectively, for an assumed $J_2 = 0.013$ for Uranus. As a consequence of the approximate Laplace relation satisfied by the mean motions of Miranda, Ariel and Umbriel⁸, several weaker Miranda-Umbriel and Ariel-Umbriel resonances also approximately coincide with the above rings. Furthermore, the 4:1 resonance with Miranda is located about 114 km inside Marsden's³ position for the ϵ_1 ring.

Despite the near coincidences between the locations of the strongest resonances and some of the rings, the rings cannot be made up of librating material. The maximum radial width of an arc of librating particles is

$$W = 8 \left(\frac{aR}{3GM} \right)^{1/2} a \quad (13)$$

From the resonance strengths, we obtain $W \approx 0.7$ km for the 4:1 resonance and $W \lesssim 0.07$ km for the strongest Miranda-Ariel resonances. By comparison, the widths of the observed rings range from 1–10 km for the inner rings and 30–100 km for the ϵ ring or

rings. Furthermore, libration occurs about a relative maximum of the potential energy in the frame rotating with the resonant mean motion. Thus, inelastic collisions among the particles would be destabilising and lead to the dissolution of a compact arc of librating material. We conclude that if the ring positions are determined by resonances, the control is more subtle than previously suggested. One possibility is that the rings are the crests of nonlinear density waves in an optically thin disk of particles. Calculations of the resonant excitation of density waves in Saturn's rings have shown that even weak resonances produce nonlinear waves⁹.

Identification of water frost on Callisto

THE 3.1- μ m absorption band of water frost has been tentatively identified in spectra of the Galilean satellites Ganymede and Callisto. This is the first positive evidence for water frost on the surface of Callisto. The depth of this absorption band on both satellites is about twice as deep as is inferred from the depths of the water frost bands at 1.5 and 2.0 μ m. Previous high resolution spectral studies ($\Delta\lambda/\lambda \sim 0.02$) of the Galilean satellites in the 1.0–2.5 μ m region have identified water frost on the surfaces of Europa (J II) and Ganymede (J III) from the presence of characteristic water frost absorption bands at 1.5 and 2.0 μ m^{1–3}. All studies failed to positively identify water frost on either Io (J I) or Callisto (J IV) but were used to set an upper limit of 5–25% (surficial coverage) for the amount of water frost on Callisto¹. The spectrum of water frost also has a characteristic band at about 3.1 μ m which is stronger than the ones at shorter wavelengths^{3–5}. Previous studies have shown a decreased reflectance between 3 and 4 μ m for Callisto, but water frost could not be positively identified because of low spectral resolution^{6,7} and poor signal-to-noise and the problem of using the Moon as a standard because of the onset of lunar thermal emission beyond 2.5 μ m (refs 1,2).

Broadband (J, K, and L) and narrowband (3.0–3.8 μ m) observations of Ganymede and Callisto were made on the nights of 7 November 1976 and 29 November 1976 (UT) with the Mount Lemmon 28-inch infrared telescope which

employs a rocking secondary mirror to chop the beam 25 arc s on the sky. The infrared observational techniques and equipment are described elsewhere⁸. The filters used are listed in Table 1 along with the zero magnitude flux calibration. α Per and β Gem were the standard stars for these observations. The standard star calibrations derived from Johnson *et al.*⁹ are given in Table 2. The standard star observations were internally consistent to better than 0.05 mag and all satellite measurements were made within 0.05 air mass of a standard star measurement. 'Intermediate' air mass corrections were used⁸. Relative infrared reflectances were normalised to $R_\lambda(1.25 \mu\text{m}) = 1.0$ after subtracting the appropriate solar colour. The solar magnitudes used are given in Table 2 and are derived from Low and Rieke⁸ and Labs and Neckle¹⁰. The log of satellite observations is listed in Table 3.

The results of the observations are given in Table 4 and illustrated in Fig. 1. The spectra clearly show an absorption feature centred between 3.1 and 3.4 μm . The band depth in the Ganymede spectrum is consistent with at least as much surficial coverage of water frost as estimated by Pilcher, *et al.*¹ and Kieffer and Smythe³. The absorption band in the spectrum of Callisto is shallower than that of Ganymede, but is of the same general shape. This indicates the presence of an optically significant amount of frost on Callisto and is consistent with a surface exposure of water frost which is somewhat less than on Ganymede.

This absorption feature is deeper than might be expected on both satellites. Assuming that the rest of the surface is covered by a 'grey' component (for example, silicate), Pilcher *et al.*¹ used the observed visual albedo and the observed depths of the 1.5- and 2.0- μm water frost features (upper limits for the case of Callisto) to determine the most probable surface coverage of water frost for Ganymede and Callisto. The depth of the 3.1- μm band can be predicted from the relative depths of the 1.5-, 2.0- and 3.1- μm water frost features, the estimated surface coverage of water frost, and albedo of the frost and 'grey' material. The predicted depth of the band is only about half as deep as observed on both Ganymede and Callisto (see Fig. 2a). One possibility is that the non-frost component has a flat relative reflectance from the visual through 2.5 μm and a lower reflectance in the 3-4- μm region. This may be indicative of the presence of dark hydrated minerals (for example, carbonaceous chondritic material) whose spectra show water absorption in the 3-4- μm region, but whose water absorption features shorter than 3 μm are suppressed by the presence of dark material (W. Salisbury, personal communication and ref. 11). Alternatively, the relative inconsistency between the band depths at 1.5 and 2.0 μm compared with 3.1 μm may be due to the intimate mixing of a significant amount of the 'observed' water frost with the 'grey' material, thus suppressing the short wavelength

Table 3 Log of Data

bands relative to the much stronger 3.1- μm band. Either of these would be consistent with the models for the formation and evolution of the Galilean satellites that predict relatively unaltered surface crust of water frost and silicates for Callisto¹².

Recent airborne telescopic observations of the Galilean satellites and laboratory studies of hydrated minerals bear out both of these possibilities. The telescopic observations covering the spectral region 1-5 μm ($\Delta\lambda/\lambda \sim 0.03$) show a very strong absorption feature centred at about 2.8 to 3.0

Fig. 2 Comparison of the relative spectral reflectance of Callisto to possible surface materials. *a*, Water frosts (absolute reflectance); *b*, montmorillonite, $(\text{Mg, Fe, Al})_4(\text{OH})_2(\text{Si, Al, Fe})_8\text{O}_{20} \cdot n \cdot 6\text{H}_2\text{O}$; *c*, Montmorillonite, cooled to about 150 K (reflectance, arbitrary units); *d*, Ratio *c/b*. For each curve, \times and \bullet represent the relative reflectances (for the filter band passes used) of Callisto and the materials in question, respectively. \circ represent the relative reflectances in the filters of a mixture of water ice and a 'grey' material as estimated by Pilcher, *et al*¹ for the surface composition of Callisto (10% water frost and 90% 'grey' material). *a* is from Smythe⁴. All other curves are from Lebofsky¹⁵. The extension of curve *b* down to 1.0 μm was taken from the results of Nash and Fanale¹⁶.

μm which has been tentatively identified as being due to water of hydration¹³. These data are consistent with the results presented here, but are not of sufficient signal-to-noise to make an absolute match.

Using X-ray diffraction techniques¹⁴ it has been shown that when hydrated minerals (bentonite-water pastes in these studies) are frozen, all but two or three monomolecular layers of the interlamellar water migrates into the pore space to form ice. Reflectance studies (1.5–4.0 μm , $\Delta\lambda/\lambda \sim 0.002$) of room temperature and frozen ($\sim 150\text{ K}$) montmorillonite and other minerals are being conducted¹⁵. Preliminary results are presented in Fig. 2, which shows that the water of hydration bands at 1.9 and 2.8 μm are decreased in strength and shifted to longer wavelengths due to the formation of water ice in the pore space. The absorption bands due to the water ice can be seen at 2.0 and 3.0–3.1 μm (Fig. 2*d*). It is clear from Fig. 2 that the hydrated minerals alone do not match the spectrum of Callisto because of the presence of bands at 1.4 and 1.9 μm and the differences in the 3–4- μm band shape, but it seems that this may be overcome by the addition of dark carbonaceous material (to suppress the 1.4- and 1.9- μm feature) and some water frost (to increase the band depth in the 3–4- μm region).

Based on the previous identification of water frost on the surface of Ganymede from shorter wavelength data, we infer the presence of water frost on the surface of Callisto from similar bands at 3–4 μm on both satellites. The depths of these bands may also indicate the presence of water of hydration, though how the frost and hydrated mineral may be mixed are as yet unknown.

I thank the University of Arizona, Lunar and Planetary Laboratory for telescope time and equipment, also Drs G. Rieke, F. Fanale, T. Johnson, D. Matson, and G. Veeder for helpful discussions. I was supported by a National Research Council Resident Research associateship during this research. This paper is JPL Planetology Publication 78-9 and was carried out under contract NAS 7-100, sponsored by the Planetary Geology Program Office, Office of Space Science, NASA.

Isotopic composition of uranium in chondritic meteorites

THE isotopic composition of uranium has been extensively measured for terrestrial U ores by precise gas mass spectrometry^{1,2}; measurements on other rock-types and minerals are limited³⁻⁵. Analyses of lunar material⁶⁻⁸ have shown the $^{238}\text{U}/^{235}\text{U}$ ratio to be the same, within experimental error, as the accepted value for terrestrial U (from pitchblende), namely 137.88 ± 0.14 (ref. 8). Measurements of the isotopic composition of U in five meteorites are reported here. The data show that variations in the U isotopic composition exist in these chondrites, and indicate the presence of components of low $^{238}\text{U}/^{235}\text{U}$ ratio. For meteorites there does not seem to have been any published attempt at a direct measurement of the $^{238}\text{U}/^{235}\text{U}$ ratio. In meteorite chronology it is generally assumed⁹⁻¹¹ that the U isotopic composition in meteorites is the same as that on Earth.

The samples used consisted of whole meteorite fragments free from fusion crust and broken from the interior of a given meteorite. A modified form of the method given by Arden and Gale¹² was used for the separation of U, which was carried out in clean-room conditions. The separated uranium was loaded, in water, on to an outgassed zone-refined V-shaped Re filament, previously completely covered on its top surface with a thin film of colloidal graphite and carefully evaporated

to dryness. Rigid control was maintained throughout on filament preparation, loading and running conditions. The mass spectrometer and ion-counting system used have been described¹².

The isotopic abundance of U, using NBS 950a standard, was measured in the range 0.2 to 20×10^{-9} g. The measured mean $^{238}\text{U}/^{235}\text{U}$ ratios ranged from 136.82 to 138.33 with a single-run internal precision of about $\pm 0.2\%$ ($1\sigma_m$). To check for any possible interference effects or suppression of emission, some runs were made after passing the U through the separation procedure and with an excess of tri-*n*-butyl phosphate. The variable mass fractionation between runs as measured by the standard deviation of replicate measurements was $\pm 0.37\%$.

The total range of U standard measurements about the mean value of 137.59 was $\pm 0.5\%$, which is similar to that obtained with the use of $^{233}\text{U}/^{235}\text{U}$ spike¹³ at the $0.1\text{-}\mu\text{g}$ U level. No measurable in-run fractionation, over the temperature range $1,600\text{--}1,700^\circ\text{C}$, was observed. The U loaded on to the filament was in a highly purified state and no residue was visible. On the standard and sample runs a 'clean' spectrum was obtained. The metal-oxide ion ratio was of the order of 1,000:1 and the ^{238}U count rates were in the range 10^3 to 0.7×10^6 p.p.s. Sample data, measured U isotopic compositions, whole meteorite concentrations and computed overall whole meteorite isotopic compositions are given in Table 1.

The results show that U in the meteorites analysed is a mixture of components of widely different $^{238}\text{U}/^{235}\text{U}$ ratios. One

* (a), Dried residue heated, in autoclave for 1–2 d at $\sim 180^\circ\text{C}$ with 7 ml of either 7M HNO₃ or 6M HCl. The solution was removed, a further similar volume of the acid added and the heating cycle repeated. The two extracts were combined. (b), As for (a), with next acid. (c), A very small residue often remained after (a) and (b). For some of the samples this residue was heated with 16M HNO₃ or 6M HCl at $\sim 180^\circ\text{C}$ for 4 d.

† Measured ratios were corrected for dead-time but not for blank. (Complete blank ~ 0.01 ng, separation blank ~ 0.004 ng.). *m*, No. of data cycles (each cycle consists of the mean of 5 measured ratios). σ_m , Standard deviation of means.

‡ Calculated using measured $^{238}\text{U}/^{235}\text{U}$ ratio, but not corrected for blank.

§ Overall $^{238}\text{U}/^{235}\text{U}$ ratio for the whole meteorite sample—computed from the total no. of atoms of the respective isotopes in each extraction.

component of terrestrial, or near terrestrial, isotopic composition is usually present at the normal abundance level (~ 10 parts in 10^9) and is readily dissolved (after HF attack) by HCl or HNO_3 . The others with lower measured $^{238}\text{U}/^{235}\text{U}$ ratios are present in low abundance in the whole meteorite, and, as indicated by the prolonged acid attack at elevated temperature and pressure required to release the components (see Table 1), seem to be contained in very resistant phases. The distribution of the latter components within the whole meteorite samples is probably very heterogeneous. Fission track studies in chondrites show that changes in U concentration by factors of 10^5 may be observed over distances of $\sim 10^{-2}$ cm (ref. 14).

The dissolution process, however, can influence the contribution made by each component to the U isotopic composition in each fraction. After decomposition, the dried complex fluoride residue is leached with a high concentration of acid at elevated temperature and pressure. This dynamic equilibrium process releases species occluded in the precipitate so that they remain in the solution phase, and has been shown to give quantitative solution of U ('major component') in HCl (ref. 12) and HNO_3 . If, however, one or more component phases are present which are attacked by HNO_3 or HCl but possibly only to a very limited extent (in these experimental conditions) by HF or HF/ HNO_3 during sample decomposition, then the rate and extent of dissolution of this phase depends on several factors. Among these are its physical state (dispersed surface coating or discrete mineral grains) actual time and length of exposure to the acid during the leaching process, as well as the activity of the acid in solutions of varying ionic strength. (The data obtained for the U standards, as well as the detailed analytical procedure used may be obtained from the author.)

Some possible mechanisms by which heterogeneities could arise are: (1) In the two-spike model, Wasserburg *et al.*¹⁵ predicted that the r -process nuclei occurred in three stages; a large amount of initial production early in the history of the galaxy, followed by a relatively quiescent period ($\sim 3 \times 10^9$ yr) terminated by a nucleosynthetic event that possibly initiated the separation of the solar system. Incomplete mixing of matter from the two events in the relatively short time interval between the predicted terminal spike at 4.8 to 4.6 Gyr and the formation of the solar system could occur: matter from the last nucleosynthetic event would have a low $^{238}\text{U}/^{235}\text{U}$ ratio. (2) The presence of grains in the solar nebula that had previous existence in the interstellar medium could, if incorporated into the meteorite parent body, result in a variable but low $^{238}\text{U}/^{235}\text{U}$ ratio¹⁶. (3) Grains with a low $^{238}\text{U}/^{235}\text{U}$ ratio could result from the explosion of a Type II supernova which could have triggered the collapse of a nearby interstellar cloud and led to the formation of the solar system¹⁷. (4) Chemical fractionation of Cm and U in some region of the early solar system. The nuclide ^{247}Cm decays to ^{235}U ; thus if a large $^{247}\text{Cm}/\text{U}$ fractionation occurred it would have produced enhancement in the abundance of ^{235}U , resulting in a low $^{238}\text{U}/^{235}\text{U}$ ratio¹⁸.

I thank M. C. B. Abranches for evaluation of the mass spectrometry of U. This study was supported by a grant from the NERC.

Stacking faults in dolomite

DOLOMITE, an important rock-forming mineral, is a mixed carbonate possessing trigonal symmetry ($R\bar{3}$), with alternate layers of Mg and Ca atoms separated by planes containing the carbonate groups. Its ordered structure offers the possibility of extended planar faults of low energy and Barber¹ has shown evidence for stacking disorder in dolomite of high metamorphic grade. There is no previous evidence, however, for the creation of extended faults as a direct result of deformation processes. We have prepared single crystals, approximately 25 mm² in cross section and 10 mm long, and tested them in compression at temperatures up to 800 °C while subjected to a confining pressure of either 3 or 7 kbar. Specimens were mostly oriented to give a large resolved shear stress on the basal planes while minimising the stress for mechanical twinning on the $f = \{01\bar{1}2\}$ planes. (We use four-digit indices for planes and directions referred to the structural hexagonal unit cell, with $c = 16.01$ Å and $a = 4.81$ Å.) It has been shown (optically)² that slip on (0001) and twinning on $\{01\bar{1}2\}$ are common modes of deformation on dolomite. Using TEM methods, Barber¹ has shown that slip on $\{01\bar{1}2\}$ can also occur in dolomite. The current observations were also made by high voltage transmission electron microscopy, using sections which were thinned first mechanically and then by ion bombardment.

The extended planar faults are generated by slip on the basal planes and when viewed with the electron beam aligned parallel to a $\langle 2\bar{1}\bar{1}0 \rangle$ direction, they are visible edge-on as very fine lines of low contrast. They are thus easily distinguishable from long screw-type basal dislocations which are profuse in most samples. By tilting a foil of known orientation, ($2\bar{1}\bar{1}0$), through a measured angle about the $[01\bar{1}0]$ zone axis (the line of intersection of a fault with the foil plane) and knowing the foil thickness, the fault plane has been shown to be unequivocally (0001). Local specimen thickness was determined easily because of the presence of small cleavage cracks on $\{10\bar{1}4\}$.

Figure 1a shows the faults in minimum contrast, using a 03 $\bar{3}0$ reflection; the dislocations terminating the faults are clearly visible. The faults also have minimum contrast for reciprocal lattice vector $g = 11\bar{2}0$. In Fig. 1b, the beam is still nearly parallel to $[2\bar{1}\bar{1}0]$, but both $01\bar{1}5$ and $02\bar{2}10$ reflections are operating to give strong fault contrast. In Fig. 1c a tilt of approximately 20° is applied to show fringed fault contrast, using $+g = 1\bar{1}08$ and $-g$, while in Fig. 1d the fault is invisible ($g = 211\bar{1}8$) and the partial dislocations are in contrast. Although these observations were taken at 1,000 kV and dolomite is elastically anisotropic, the clarity of these contrast changes strongly suggests that we can calculate the displacement vector R in the usual manner, taking $g \cdot R = n$, where n must be zero or an integer for zero contrast with a given reciprocal lattice vector g . Using the above data, this gives as a likely value for R the vector $\frac{1}{3}[1\bar{1}00]$, which is not a proper translation vector of the dolomite structure. As might be anticipated, the vector lies in the basal plane and, for example, when applied to a magnesium atom, translates it at 30° to the normal $[1\bar{2}\bar{1}0]$ slip vector to a position directly above a calcium atom. This creates a stacking fault in the structure (not an antiphase boundary): the stacking fault is removed with a further displacement of $\frac{1}{3}[01\bar{1}0]$, giving

$$\frac{1}{3}[1\bar{1}00] + \frac{1}{3}[01\bar{1}0] = \frac{1}{3}[1\bar{2}\bar{1}0]$$

which is the normal slip vector of length 4.81 Å. This reaction, of course, identifies the observed partial dislocations. We have

Fig. 1 Basal stacking faults in dolomite single crystal 4071 XD, compressed at 500 °C under a confining pressure of 3 kbar to a strain of 2.5% at a strain rate of 10^{-5} s^{-1} . The foil plane is (2110) and the faults are imaged at 1 MeV in various diffraction conditions: *a*, 0330 reflection; scale bar, 1 μm ; *b*, 0115 and 022.10 reflections; *c*, 1108 and 1108 reflections; *d*, 211.18 reflection.

found that such stacking faults occur extensively in dolomite crystals compressed at temperatures of 300–500 °C.

We have also observed that faint fringe contrast is sometimes created by the passage of dislocations on the {0112} slip planes. We have failed, however, to find a diffraction vector which brings the fringes into strong contrast and the fringes do not always terminate at dislocations but sometimes extend throughout the active part of the slip plane. It thus seems that the faint fringes, which indicate residual elastic strain, may be associated with a small fractional displacement vector, as occurs in orthopyroxene³.

Evidence for stacking faults generated by slip in carbonates is new and it further emphasises the differences in mechanical behaviour between dolomite and calcite⁴. Until the work of Turner and Orozco⁵ on metamorphic calcite there was no firm evidence for basal slip in calcite, although it is the favoured low-temperature mechanism in dolomite. Braillon and Serughetti⁶ have reported small (0001) planar faults in calcite but have attributed them to growth twinning. Our results, which demonstrate the existence of extensive stacking faults in dolomite, together with partial dislocations, are therefore novel and important.

The work was supported by SRC grant GR/A 14599. We thank E. Amundarein, Magnesitas-Navarra, for dolomite crystals.

Acoustic imaging of the New England shelf-slope water mass interfaces

PULSED high frequency acoustics has been shown to have unique applications in the detection and measurement of oceanic phenomena such as internal waves¹⁻³ and dispersion of ocean-dumped sewage sludge^{4,5} or dredge material⁶. With moderate to high pulse repetition rates, a virtually continuous record of water column scattering strength is available to depths of the order of 500 m from a ship travelling at speeds of 4 or 5 knots. We used this feature to detect acoustically the interfaces associated with an intrusion of cold New England shelf water into the warmer slope water during a 9-d period in June 1976.

From 15 to 23 June 1976 measurements of effects of internal waves were made from the National Oceanic and Atmospheric Administration (NOAA) ship George B. Kelez in an area on the New England continental shelf partly shown in Fig. 1. Although measurements were made on three tracklines shown, most of the work concentrated on the centre trackline. A 1-kW 20-kHz pulsed acoustic system, specially modified for detection of weak signals scattered from the water column, was operated continuously throughout the cruise. Field operation of this system has been described previously^{4,7}. Profiles using expendable bathythermographs (XBT) and a conductivity-temperature-depth probe (CTD) were obtained at regular intervals.

Throughout the cruise, the acoustic record revealed a reflecting layer (Fig. 2) of limited horizontal extent and

Fig. 1 Region of New England continental shelf where water mass interfaces were observed. Contours are in fathoms, dashed lines are tracklines along which most work was performed. X with a date denotes an observation of the intersection of the scattering layer offshore boundary and the ship's trackline. The light dashed lines represent the width of the intrusion observed on 22 June.

rather variable location. Some observations of the offshore boundary of this layer are indicated in Fig. 1. The layer was observed in all cases (18 observations) to have a slope opposite to that of the bottom. As shown along the ship's trackline, the layer displayed apparent widths of 2.8–7.4 km. The last few records (for example, Fig. 2) of the scattering layer also show a second layer higher in the water column and parallel to the surface, but apparently descending to join the ascending lower layer at their offshore boundary. This made a sufficiently dramatic feature to finally get our attention. We then obtained XBT and CTD profiles through the feature when the cruise plan permitted.

A series of three XBT profiles (Fig. 3) across the layers revealed that they occur in a region of transition between two distinct water masses. XBT 99 shows the bottom shelf water to have a temperature of about 7 °C while XBT 104 shows the minimum temperature of the deeper slope water to be about 10 °C. XBT 103, taken in the region where the layers were present shows interleaving of 7 °C water with 10 °C water. The depths of the upper and lower steep

Fig. 2 A portion of the acoustic image showing the scattering layers associated with the intrusion interfaces (frequency 20 kHz). The left portion of the image, with darker background, represents a distance of 5.6 km. The portion to the right of the interrupted bottom signal was made with the ship on station for a CTD profile. The CTD echo signal is visible on the image.

temperature gradients in XBT 103 coincide with the depths of the acoustically reflecting layers measured at the moment the XBT 103 profile was taken. The gradient depths of XBT 103 (taken at 0729 GMT, 22 June) may be compared with the depths of the reflecting layers in Fig. 2, observed at 1325 GMT, 22 June. The slightly later acoustic image was chosen for its higher quality and clearer manifestation of the layers joining at the offshore boundary. In the right hand portion of Fig. 3 (the region of lighter background), the Kelez took station and a CTD profile was made and can be seen falling and then rising through the layers. The CTD temperature profile was similar to XBT 103 but showed very much steeper temperature gradients at the top and bottom of the 7 °C intrusion.

The horizontal transition from 7 to 10 °C water is a familiar feature. It is well known⁸ that by June the surface shelf water has warmed due to increased net solar radiation while the bottom shelf water remains cold, typically about 7 °C. The slope water is not cooled as much during winter mixing and has a minimum temperature of about 10 °C. During winter the shelf-slope water front is a well formed feature⁸, but spring surface warming over the shelf and slope removes the horizontal temperature contrast except in the lower water column. The reflecting layers manifested in the acoustic image are associated with nearly horizontal interfaces formed by interleaving of the shelf and slope water masses during spring and summer.

The location of the shelf-slope water interface on the centre trackline migrated about 18 km northwards during the nine-day span of observations. Reflecting layers observed on 15 and 16 June were confirmed to be shelf-slope water interfaces by XBT pairs (7, 8, and 17, 18 respectively) taken north and south of the observed layers. On 17 June a layer observation on the western trackline, confirmed by XBT 26 (not shown on map) and XBT 27, showed the shelf-slope

Fig. 3 Three XBT profiles (locations shown in Fig. 1) showing the changing make-up of the water column across the region in which acoustic scattering layers were identified as shelf-slope water mass interfaces. The temperature scale is actually three scales joined at the 20 °C points.

water interface to be further south. We observed no reflecting layer associated with the water-mass interface on the eastern trackline but found the transition took place between XBT 46 42° 32'N and XBT 47 on 18 June. It would seem, then, that the shelf-slope water transition zone was in a north east-south west direction in the vicinity of this experiment. Curiously, from 19 through 22 June the deep water boundary of the transition zone was roughly stationary as shown in Fig. 1. Thus the boundary moved 18 km along the centre trackline from 16 to 19 June and moved very little in the next four days.

The shelf-slope water transition zone apparently fluctuates significantly in location on a time scale of a few days. Also, Cresswell¹⁰ has observed distinct parcels of shelf water in the deeper slope water indicative of a mixing process. If the conditions for scattering at these water mass interfaces are often suitable for acoustic scattering, it may be possible to observe acoustically the shelf-slope water exchange process occurring in the summer on the New England continental shelf. XBT and CTD profiles would be needed only occasionally to confirm that the scattering layers are the interfaces of interest. Most of the ship time would then be spent covering the area of interest in a regular fashion with sufficient frequency to resolve water mass movements as they occur.

Effect of climate on chemical composition of fossil bones

THE suggestion that microanalysis of nitrogen, fluorine and uranium in fossil bones should be used for age determination¹⁻⁴ assumes that the concentration of these elements varies uniformly in time. Vonach⁵ has plotted calibration curves for the N and F content of fossil bones from the past 10⁴ yr. The nitrogen content, N , can be approximated by

$$\log N = -0.135 \log t + 0.681$$

where N is weight per cent and t is age in years. The chemical changes that occur in buried bones depend on the composition of the surrounding minerals and the environmental conditions⁶. The concentration of a given element in bone is also influenced by biochemical differences between samples. Consequently, large fluctuations in N can be expected around the gross trend described by Vonach. We report here a fluctuation of the N content of bones that seems to correlate with climatic change.

Fig. 1 N content of bones as a function of absolute age. . . . x . . . , Our results; ●, at 3,100 yr and —, from ref. 5.

We investigated the concentration of N, Fe, Al and Ca in bones from the past 9,000 yr. We chose this time interval because of the relatively large number of dated samples found and the significant climatic change during the interglacial phase. We used human vertebrae of known ages buried in the Great Hungarian Plain.

The N, Fe and Al content was determined by fast and thermal neutron activation analyses using the $^{14}\text{N}(n,2n)^{13}\text{N}$, $^{56}\text{Fe}(n,p)^{56}\text{Mn}$ and $^{27}\text{Al}(n,\gamma)^{28}\text{Al}$ reactions, respectively. The

Fig. 2 Corrected N content of bones (. . . x . . .) and the sea level difference (straight lines) as a function of calendrical time.

Fig. 3 Corrected N content of bones as a function of sea-level difference. $N = 4.1405 \exp(-0.26\Delta H)$.

concentration of Ca and Fe was measured by X-ray fluorescence using an Si(Li) detector and ^{55}Fe and ^{125}I exciting sources. Figure 1 shows N content as a function of the age of the bone. There is a fine structure (dotted curve) superimposed on the Vonach's gross trend (continuous curve).

Fig. 4 Concentration of Al(▲), Fe(●) and Ca(×) in bones as a function of calendrical time.

The fluctuations in the data cannot be explained by biochemical differences between individuals and the uncertainty in the determination of N, for which the error does not exceed $\pm 10\%$. Results of *in vivo* neutron activation analysis of patients have shown that deviations in N content are less than $\pm 30\%$ even for different diseases^{12,13}.

There seems to be a periodicity of about 2,000 yr between the minima of the fluctuations. Accepting the gross trend for N content, we normalised the measured data to the date of burial. It should be noted, however, that the corrected N contents in some cases are abnormally larger than those obtained for modern bones. These normalised values and the sea-level differences, ΔH , from the present-day value⁷⁻⁹ are given in Fig. 2 as a function of calendrical time. An extremely high value of sea level (9 m) was given by Brooks¹¹ for 500 BC. Figure 2 shows a correlation between N content and sea level. The correlation can be approximated

by the following relationship: $N = 4.1405 \exp(-0.26\Delta H)$ (Fig. 3). Brooks has pointed out a linear correlation between climate and sea level. On the basis of the data for sea level⁷ and temperature⁹ for the interval from 1,000 BC to 5,000 BC, a value of $\Delta H/\Delta T \sim 2.6$ m per °C can be estimated. It can be concluded that the minima in N content indicated in Fig. 1 coincide fairly well with the climatic maxima. It seems to be a correlation between the 'neo-glacial cycle'¹⁰ and the N content of bones. The deviations from the predicted solid line in Fig. 1 can be attributed to the change in the climate of the age from which the bones originate.

The measured values for Al, Ca and Fe content of human bones as a function of calendrical time are given in Fig. 4. Both the trends and the absolute values for iron measured by X-ray fluorescence and neutron activation are in good agreement within $\pm 5\%$, proving the reliability of the methods applied. Figure 4 shows changes in the concentrations of all the elements investigated.

An opposite trend is shown for Fe and Al on the one hand, and Ca and N on the other hand. Chemical separation showed that the Fe and Al contents belong to the organic part of the bone.

We thank Professor J. Nemeskéry for discussions and for bone samples.

Physiological exclusion of magnesium from *Mytilus edulis* calcite

CALCITE produced by many marine organisms (including molluscs¹, brachiopods², coccolithophorids³, and planktonic foraminifera^{4,5}) contains only about 5% as much magnesium as is predicted by laboratory studies of distribution coefficients^{6,7} (ratio of the Mg : Ca ratio in the solid against that in the solution). Understanding the cause of this low magnesium content is important to our comprehension of the calcification process. It is also of considerable interest to the field of low temperature geochemistry for several reasons. First, calcite is the major authigenic component of marine sediments, and its magnesium content is an important feature of its bulk composition. Second, the controls on the magnesium content of invertebrate skeletal must be understood if Mg : Ca ratios of calcitic fossils are to be used as indicators of sea salt palaeochemistry⁸ or sea surface palaeotemperature⁹. Third, the mechanism of magnesium inclusion may determine the role of magnesium in regulating selective dissolution of the tests from planktonic foraminifera⁴. Fourth, since calcite solubility depends on the magnesium content of the calcite, the mode of magnesium inclusion is a factor to be considered in calculating the degree of carbonate saturation in the

oceans. Finally, factors governing the mode of magnesium incorporation into skeletal calcite are important to sedimentary petrologists using magnesium as a diagenetic indicator. We report here that the mussel *Mytilus edulis*, which normally secretes low magnesium calcite, incorporates anomalously high amounts of magnesium into its calcitic shell layer when it is grown in solutions of higher than normal magnesium content. Thus in normal conditions *Mytilus* physiologically excludes magnesium from its shell-forming fluid, and at higher magnesium concentrations ion regulatory systems breakdown, causing a substantial increase in the amount of magnesium coprecipitated into *Mytilus* shell calcite.

Young *M. edulis* (7–15 mm long) were collected from Narragansett Bay, Rhode Island and cultured for 8 weeks in aerated 4.5-l glass aquaria. The water was changed at weekly intervals and the mussels were fed a suspension of *Isochrysis*. Twenty mussels were placed in each tank. The culture solutions were prepared by mixing one part natural seawater with one part synthetic 'seawater'. A range of Mg : Ca ratios in the culture solutions was obtained by changing the proportions of sodium and magnesium in the synthetic 'seawater' solution. A constant total ionic strength (0.64 ± 0.04 M) could then be maintained between different composition solutions while also maintaining a constant calcium concentration similar to that of seawater (9.3 mM) in all the solutions except the lowest Mg : Ca ratio solution. To make the lowest Mg : Ca ratio solution (Mg : Ca = 0.75) a calcium concentration of 33 mM was used in the culture solution.

M. edulis forms both calcitic and aragonitic shell layers. Calcite samples of shell grown during this experiment were collected from the newly grown calcitic-shell edges outside the pallial line. These samples were analysed by atomic absorption spectrophotometry for magnesium and calcium^{5,9}. Ratios of the molar concentrations in both the solution and shell are reported since the ratios more clearly show the relative fractionation effects between the two ions. The growth of each mussel was recorded by measuring its length at the beginning and end of the experiment.

The Mg : Ca atom ratios of the newly grown shell are compared with those of the culture solutions in Fig. 1. Normal seawater has a Mg : Ca ratio of 5.2. Mussels grown in artificial media with the same Mg : Ca ratio as natural seawater produce the same shell Mg : Ca ratio as a control set of mussels grown in 100% natural seawater. Mussels grown in solutions with a Mg : Ca ratio less than 7 show a gradual increase in the shell Mg : Ca ratio with increases in the solution Mg : Ca ratio, except for the lowest solution ratio sample which has a slightly elevated shell ratio. As the Mg : Ca ratio of the solution increases above 7 there is a dramatic increase in the amount of magnesium incorporated into the shell.

Inorganic distribution coefficient data cannot account for the Mg : Ca ratios of the shells. Distribution coefficient data determined by Katz⁷ for low Mg : Ca ratio solutions predict that calcite precipitated from a solution with a Mg : Ca = 0.75 (the lowest ratio tested) will have a calcite Mg : Ca ratio of 40×10^{-3} ; this is 20 times more magnesium than we find in *Mytilus* shells grown in these conditions. Studies of the inorganic precipitation of calcite from seawater reveal Mg calcites containing >10 mol per cent MgCO_3 (ref. 6), although Berner⁶ suggests that 2–7 mol per cent MgCO_3 is the most stable composition in the presence of seawater. Distribution coefficient data are not available for solution Mg : Ca ratios of >5. But, surface-solution equilibrium exchange data show that near a Mg : Ca solution ratio of five surface distribution coefficients decrease¹⁰; if this is any guide, we would also expect bulk distribution coefficients to decrease. The increase in mag-

nesium observed in our experiments is directly opposite to this expectation and suggests that inorganic processes are not responsible for regulating the magnesium content of *Mytilus* calcite.

Growth rate has been suggested as a factor controlling the inorganic composition of calcified tissues¹¹. A range of growth rates was observed for the mussels cultured in each Mg:Ca ratio solution. Mussels in the two lowest Mg:Ca ratio solutions grew slowly and only a few grew sufficiently to allow sampling (≥ 1 mm new growth). Mussels in the other solutions examined grew at about the same rate (from 1 to 4 mm in length in 8 weeks). Mussels placed in a solution with a Mg:Ca ratio of 13.5 did not grow. There was no correlation between growth rate and the shell Mg:Ca ratio of mussels grown in the same solution. High Mg:Ca ratios did not significantly influence growth rate except in the one case noted above. In this experiment growth rate was not a factor influencing the magnesium composition of *Mytilus* shell calcite.

Fig. 1 The calcite shell Mg:Ca atom ratio for each mussel plotted against the Mg:Ca atom ratio of the solution in which it was grown. ○, Samples of mussels grown in natural seawater; ●, mussels grown in synthetic medium. × Represents the metal ratio determined from a composite sample by X-ray diffraction.

Anomalous increases in the magnesium content of these calcite shells could occur if another mineral phase such as brucite ($\text{Mg}(\text{OH})_2$) or hydromagnesite ($3\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$) were precipitated; we carried out X-ray diffraction studies to check this possibility. Mussels grown in 100% natural seawater were almost pure calcite ($d_{211(104)} = 3.035 \text{ \AA}$), whereas a sample taken from mussels grown in the highest Mg:Ca ratio solution had a d spacing of 3.027 \AA . This change in d spacing corresponds to a 2.5 mol per cent increase in MgCO_3 , as calculated from data showing the dependence of d spacing on calcite magnesium content¹². From this increase a Mg:Ca ratio of 31×10^{-3} is calculated for the high magnesium calcite sample. While this ratio falls a little short of the Mg:Ca ratio determined by atomic absorption, it is still several times greater than the ratio that would be obtained by a linear extrapolation from the origin through the normal

seawater ratio (see Fig. 1). The only other peak observed in the high magnesium sample had a d spacing of 17.67 \AA . This d spacing does not correspond to any magnesium containing mineral listed in the tables of the American Society for Testing Materials. High d spacings are often associated with organic material; whether or not this peak represents an elevated shell organic matrix content and whether or not magnesium is associated with it, is conjecture at this point. The X-ray data are in agreement with the atomic absorption data and indicate that an anomalous increase in the coprecipitation of magnesium into *Mytilus* calcite occurs when mussels are grown in solutions containing a higher than normal magnesium content.

Magnesium in high concentrations inhibits the nucleation¹³ and growth⁶ of calcite. Simkiss¹⁴ proposes that the mantle of some molluscs may regulate the flow of material to the crystallisation site so as to exclude crystal growth inhibitors such as magnesium and inorganic phosphate ions. We suggest that *Mytilus* does in fact have the capacity to extensively regulate the magnesium ion activity of the solution from which its shell calcite is grown. *Mytilus* may attempt to maintain an optimum magnesium and calcium composition in this fluid. In normal seawater conditions *Mytilus* produces a low magnesium calcite as a result of this ion fractionation process. At very low Mg:Ca solution ratios the ion fractionation process may discriminate less against magnesium so that the normal, or close to the normal, solution composition is maintained. This is suggested by the slightly elevated shell Mg:Ca ratio at the lowest solution ratio. When *Mytilus* is exposed to Mg:Ca solution ratios much above those of normal seawater, its ion regulatory capability apparently becomes overloaded and breaks down, thus allowing an influx of magnesium ions into the fluid from which new shell is precipitated. The result, as shown in Fig. 1, is a dramatic increase in the amount of magnesium found in *Mytilus* shell calcite.

While data are not available on species other than *Mytilus*, it is probable that other marine organisms which produce low-Mg calcite, such as planktonic foraminifera and coccolithophorids, do so by a physiological fractionation process rather than as a result of any inorganic processes.

We thank Pierre E. Biscaye for performing X-ray diffraction work. We also thank the staff of the Rhode Island Nuclear Science Center for their assistance, A. N. Sastry for animal culture facilities, and M. E. Q. Pilson for reviewing the manuscript. N.S.F. provided financial support (DES37125).

Polonium and plutonium in an intertidal food chain

LARGE quantities of seaweeds (kelp) are washed ashore along the coasts of California. Estimates range from 10^4 to 10^6 tonnes (10^7 – 10^9 kg) wet weight per yr. These algal masses provide food for insects and other invertebrates on the beaches. The plants carry with them a variety of di-, tri-, and polyvalent cations of heavy metals, largely adsorbed or chelated to superficial acidic polysaccharides and surface slimes of bacterial origin. Among the heavy metals one can detect small amounts of radioactive elements, including some that emit high-energy α particles such as the natural polonium (^{210}Po , half life 138 d) and the artificial plutonium nuclides ($^{239,240}\text{Pu}$, half lives 24,360 yr and 6,580 yr respectively)¹. In surface waters of the oceans, polonium is born from the decay of ^{210}Pb which is continuously replenished by decay of radon released from the Earth's crust. The plutonium isotopes occur in ocean waters as a consequence of fallout from atomic test explosions some 15–20 yr ago. We have examined the extent to which these elements may be transferred from the ocean to the terrestrial biosphere by means of kelp, kelp flies and their predators. Fears have been expressed that radioactivity from the algae could be reaching man through the terrestrial food chain. Our investigations suggest that, on the basis of current radiation thresholds for human health and safety, such fears are groundless.

Samples of cast weed, largely comprising blades and stipes of *Macrocystis pyrifera* (L.) C.A. Ag. but containing also a few per cent of *Egria laevigata* Setch. and *Pelagophycus porra* (Leman) Setch. and marine grasses (*Phyllospadix* and *Zostera*), were collected from the beach at La Jolla, California, in June and August 1975, at a time when kelp flies were much in evidence. Adult flies (mostly *Fucilia rufitibia* Stein and *F. separata* Stein) were caught over clumps of decaying weed by the use of a 1-mm mesh nylon net. About 30,000 flies, weighing 100 g wet weight (27 g dry weight) were collected in about 30 min. A few of the associated predatory tiger beetles (*Cicindela* sp.) were also netted, as individuals, on nearby sand. For comparative purposes we also obtained some 50 g (dry weight) of common houseflies (*Musca domestica* L.) which had been raised in a laboratory (Department of Entomology, University of California, Riverside) on a commercial fly-larva medium (CSMA, Ralston-Purina Co.).

All samples were dried in an oven at 80 °C overnight. Polonium and plutonium were determined in subsamples of 1.0 g and 20.0 g respectively. The flies and beetles were 'wet-ashed' by heating in a mixture of nitric and perchloric acids. As markers, ^{208}Po and ^{242}Pu were added to monitor the chemical recoveries of ^{210}Po and $^{239,240}\text{Pu}$ from the samples. The α activities of these elements were measured with silicon surface-barrier detectors in combination with pulse-height analysers.

As shown in Table 1, the contents of polonium in laboratory-raised houseflies, and in the diet on which they were raised as larvae, were negligible (10 and 30 pCi per kg dry weight) compared with the kelp flies (250 pCi per kg dry weight). The polonium content of the kelp flies from the beach was found to be about half of that of the cast weed, on the basis of comparable dry weights. (That of laboratory-reared *Musca* was about one third that of their larval food.) This proportional reduction may be attributable to mechanical selection by the fly larvae of the softer, interior parts of the seaweeds, which have been shown to contain considerably less of the adsorbed heavy metals (including polonium) than the surface layers². Alternatively, there may have been discrimination against uptake of polyvalent metallic cations in the insect gut, selective metabolic processes in the tissues, or active excretion of such cations.

The polonium content in the predatory tiger beetles was found to be about one-half that of kelp flies, a fact which may be attributable to similar mechanical or metabolic discrimination. (It would be interesting to determine the polonium content of other predators of kelp flies, for example birds such as spotted sandpipers (*Petrochelidon pyrrhonota*) or swallows (*Hirundo rustica*), but we did not attempt this.) In neither of the two successive steps

of the food chain studied here did we observe a relative enrichment of the radionuclides. On the contrary, at each step the relative polonium concentration was halved, while the plutonium (and ^{210}Pb) content of the kelp flies was also only half that of the content of the decayed kelp on which they fed.

A crude extract of the blood, gut contents and other soft parts of the kelp flies was prepared by homogenising a sample of the fresh flies in a Waring blender with distilled water for 45 s and centrifuging at 13,000 r.p.m. (20,000g) for 10 min. The liquid fraction was then clarified by filtration. The residues retained by the filter and at the bottom of the centrifuge tube consisted of cuticles, heads, wings, legs and bristles. This fraction contained essentially all of the polonium of the intact flies (see Table 1), indicating that most of the polonium ingested by the insect larvae with their food (the decaying kelp) had been incorporated in the cuticles of the adult flies.

In ascending the food chain from the kelp to the flies, the Po/Pu ratio remained unchanged. In contrast, corresponding values for *Macrocystis* plants and for bryozoa removed from their surfaces were respectively 230 and 1,000¹, while even larger ratios, as high as 10^5 or 10^6 , were found in the internal organs of several species of marine fishes (V.F.H., unpublished), suggesting that in these latter systems there is a more effective discrimination against Pu, or in favour of uptake of Po, or both, than in the kelp flies.

Our observations indicated that on a warm summer day there may be as many as 10^7 flies per km of beach near the Scripps Institution of Oceanography, in an area where the estimated annual tonnage of cast weed is about 10^5 kg km⁻¹ (ref. 3). The kelp brings with it some 10^7 pCi of polonium and 4×10^4 pCi of plutonium per km of beach annually. If we assume that there are 10 generations of kelp flies per yr (in summer⁴ a generation time of kelp flies may be as short as 10 d), it can be calculated that about 0.2% of the polonium and 0.2% of the plutonium adsorbed or in some other way fixed to the major seaweeds may find its way into a terrestrial food chain.

It should be emphasised that although the kelp flies may occur in large numbers along beaches on warm days, such as those observed during the great seaweed-fly plague in southern England in 1953–54⁵, the radiation values with which we are concerned here present no obvious hazards to human health. The accidental inhalation of a few kelp flies would involve the ingestion of merely 10^{-4} pCi of ^{210}Po and 10^{-6} pCi of $^{239,240}\text{Pu}$, while the deliberate ingestion of tens of thousands of such flies would be too involved and unappetising an exercise to consider seriously.

We thank Dr Willis W. Wirth (Smithsonian Institution, Washington) for identifying the kelp flies, and Mr Ian Moore (University of California, Riverside) for providing laboratory-reared houseflies and the larval medium.

Free-running activity rhythm in the natural environment

RHYTHMICAL activities of plants and animals in their natural habitats have, so far, always been found to be synchronised with cyclic environmental changes¹⁻³. In the absence of appropriate environmental timing cues (usually light-dark or tidal cycles) the rhythms free-run with endogenously controlled periods other than those of the environmental cycle. These may be longer or shorter than those observed in the presence of the entraining environmental cycles. We describe here an apparently unique example of an invertebrate which seems to free-run in its natural habitat. The animal is a predatory prostigmatid mite (*Bdella interrupta* Evans) which inhabits marine salt marshes and is exposed to regular tidal inundation during periods of spring tides. During periods of neap tides the salt marsh is not covered by the sea. The mites showed day and night peaks of locomotory activity on the soil surface at creek edges (Fig. 1a) and, also, in isolated experimental conditions (Fig. 1b). The narrow peaks of activity imply that the individual members of the population are closely synchronised with one another.

The peaks of locomotory activity in the natural habitat did not exhibit constant relationships to the times of dawn and dusk. The interval between day peaks of activity during a sequence of non-covering tides was less than 24 h. The slope of the regression line for the first 6 d illustrated in Fig. 2 corresponds to an average separation of 23.1 h between successive day peaks during this period of non-submerging tides. During

Fig. 1 *a*, Numbers of mites observed walking on the soil surface on the edges of a drainage channel on Hut Marsh, Scolt Head, Norfolk, UK. Observations were made on a 25-m length of bank during a period of tidal emergence (6-7 April 1976). The times of high tides are indicated by open arrows. Dawn and dusk are shown by broken lines. *b*, Surface activity of *B. interrupta* in isolated habitat portions (in five cylindrical containers of 15.2 cm diameter containing soil of 10 cm depth). The mites were maintained in natural light conditions.

the subsequent period of submerging tides the average separation between successive day peaks increased to 25.1 h, so that the surface locomotory activity of the mites effectively paralleled the times of the high tides for the period (Fig. 2).

Periodograms for the 1976 data illustrated in Fig. 2 yielded activity peaks at 22.9 h (for locomotory activity during non-submerging tides) and 24.9 h (during the subsequent period of submerging tides) (Fig. 3) for data collected during the daylight hours. Field observations made in 1977 confirmed these differences in periodicity observed during periods of tidal emergence and submergence. Since the activity peaks occur twice

Fig. 2 The timing of day activity peaks related to the time (●) and the height (○) of high tides from 6 to 18 April 1976. The horizontal bars indicate the period during which mite activity was more than 50% of the maximum. The vertical lines are the midpoints of the bars and are taken as the phase reference point. The open bars represent activity during tidal emergence and the closed bars that during a subsequent period of submerging spring tides. The continuous lines are the calculated regression lines (for the period of tidal emergence: $r = 0.9720$; $n = 6$; $P < 0.005$; for the period of tidal submergence $r = 0.9923$; $n = 7$; $P < 0.001$). For these calculations the day sequence was used as the x axis.

daily and the rhythm entrains to the tidal frequency when the animal is exposed to tidal inundation the locomotory activity rhythm can be defined as a circatidal rhythm with a periodicity of about 12.5 h. As with circatidal rhythms in other organisms, the mite rhythm is insensitive to light-dark cycles. In this respect this salt-marsh mite is similar to an oribatid mite (*Ameronothrus marinus* Banks), which on rocky shores shows an apparently circatidal rhythm of 12.3-h periodicity⁴.

The novel feature revealed by this investigation is that during periods of non-submerging tides the period of the activity rhythm (11.5 h) is shorter than when it is entrained by the tides (12.5 h) and can be reasonably presumed to be a free-running circatidal rhythm. The maintenance of narrow peaks of activity throughout periods of tidal emergence indicates that the periods of the individuals are very similar whilst free-running. This contrasts with the breakdown of synchrony seen in free-running populations of other organisms in constant experimental conditions.

There is no conclusive evidence that the alternation of an apparently free-running rhythm, during tidal emergence, with an entrained rhythm, during periods of tidal submergence, is of adaptive value. It is conceivable, however, that this alternation could be a mechanism to achieve synchrony with the pattern of tidal coverage on the marine salt marsh. At the onset of periods of tidal coverage the activity peaks occur approximately midway between the times of successive high tides. This temporal separation is maintained during subsequent periods of tidal coverage by the circatidal rhythm of 12.5-h periodicity. The alternation between 11.5- and 12.5-h periodicities ensures

Fig. 3 Periodograms of data illustrated in Fig. 2, for the observed locomotory activity during periods of non-submerging (a) and submerging (b) tides.

that a peak of mite activity is continuously maintained in daylight hours. This would not occur if the circatidal periodicity (12.5 h) continued during tidal emergence. Calculations using data from the 1977 tide tables show that with an intermediate free-running period, for example 12.0 h, the activity peak is always within 2.5 h for the first, critical, tidal inundation in a series of rising spring tides. With a free-running period of 11.5 h, on the other hand, the activity peak is within 2.5 h of only 17% of the critical tides.

We thank Drs Jack Benson and J. Brady for helpful discussions. We also thank the Nature Conservancy for permission to work on the Scolt Head Nature Reserve.

Sexual dimorphism, socionomic sex ratio and body weight in primates

BECAUSE the primates are a particularly well studied group they provide a rare opportunity to investigate the adaptive significance of species differences in sexual dimorphism in body size. We describe here an investigation of the relationship between the degree of sexual dimorphism and three variables which are predicted might affect it.

In many birds and mammals (with certain exceptions)^{1,2} the male is larger than the female. The commonest explanation for this trend, originally offered by Darwin in 1871 (ref. 3) is that increased body size confers advantages in contests between males for access to females (and there is now detailed evidence supporting this⁴⁻⁶). The basis of this argument is that males are able to enhance their breeding success greatly by maintaining exclusive breeding access to several mates³, whereas females cannot usually⁷ enhance theirs to the same extent by maintaining exclusive access to multiple males. For this reason, the argument runs, polyandry is rarer than polygyny. Once polygyny has developed, males will compete for access to females⁴ and individuals possessing traits which enhance their competitive ability (such as increased body size) will be selected. This argument assumes that increases in body size are constrained by ecological, perhaps energetic, disadvantages which can be outweighed by reproductive advantages.

There is another functional explanation of sex differences in body size—these may permit the sexes to utilise different kinds of food and consequently enhance the efficiency with which they can exploit their resources. These two theories are not mutually exclusive, but their predictions differ: the first predicts that sexual dimorphism should be most marked in strongly polygynous species where competition between males for access to females is intense since only a small proportion of males can breed; the second, that dimorphism should be most marked in monogamous species or in those with a relatively equal adult sex ratio where divergence between the sexes would be most effective^{8,9}. While there is reasonable evidence implicating the second explanation in particular cases⁸, the distribution of dimorphism across species generally fits the predictions of the first: monogamous species show least dimorphism and those with the most imbalanced socionomic sex ratios (the number of adult females per adult male in breeding groups) the most.

But, although a positive relationship between body size dimorphism and socionomic sex ratio has been suggested in reviews of birds^{1,10,11}, ungulates^{12,13} and primates¹⁴⁻¹⁶, none have offered formal statistical evidence for such a relationship. That such evidence is necessary is demonstrated by the extent to which species with similar breeding systems differ in their degree of body size dimorphism (see below). Also, it is necessary to investigate what other factors affect the degree of size dimorphism and to consider the possibility that the apparent relationship between dimorphism and socionomic sex ratio is the product of some third factor associated with these two variables.

In most orders, formal comparisons are impossible because of the paucity of accurate data about social organisation. This is not so in the primates, where the social behaviour of a large number of species has now been studied in detail. To examine this relationship, we extracted as many estimates of body weight and of breeding sex ratio from the literature as we could find (the sources and data used will be published elsewhere (refs 17, 18 and B. Rudder, in preparation), selecting weights of wild animals in preference to those collected from zoos wherever possible. Sexual dimorphism was then calculated by dividing male weight by female weight. Our measure of socionomic sex ratio was the mean number of adult females per adult male in breeding groups: where several estimates were available for the same species, we took the mean of these. Our sample included 42 primate species.

There is a significant relationship between sexual dimorphism and socionomic sex ratio (Fig. 1: $r_s = 0.610$, $t = 4.87$, 40 d.f., $P < 0.001$) but, this relationship is largely due to the fact that

monogamous species show consistently less dimorphism than polygynous ones (Kruskal-Wallis $H = 22.16$, $P < 0.001$) and, when monogamous species are excluded, no relationship exists ($r_s = 0.087$, $t = 0.44$, 27 d.f., not significant). Why should this be the case? There are probably two main reasons. First, socionomic sex ratio fails to provide a reliable index of inter-male competition. It would, for example, be likely to underestimate the degree of competition in multi-male troops (as in *Papio* or *Macaca* species) where a marked dominance hierarchy exists and breeding access is not shared equally among the males. Conversely, it would overestimate the degree of competition in species where access to females is strongly age-dependent and the majority of males pass through a short reproductive phase¹⁹. Also, our data will inevitably have included a proportion of cases where estimates of socionomic sex ratio were a typical, thus introducing error. Second, the data show that factors apart from socionomic sex ratio exert a strong influence on the degree of sexual dimorphism. Terrestrial species show consistently greater dimorphism than arboreal ones (Kruskal-Wallis $H = 8.96$, $P < 0.01$) probably because, in the former, increased weight does not restrict the male's access to food supplies (often located on fine terminal twigs) to the same extent as in the latter. In addition, sexual dimorphism is positively related to body weight (the mean of adult male and adult female body weight: see Fig. 2: $r_s = 0.484$, $t = 3.50$, 40 d.f., $P < 0.01$). This relationship is not a product of the inclusion of female weight in both parameters: if male weight is plotted against

female weight, the slope is significantly greater than 1 ($b = 1.063$, $t = 66.33$, $P < 0.001$). Nor is it the product of either of an association between large-size and terrestriality since the same relationship holds within arboreal species (Fig. 2: $r_s = 0.395$, $t = 2.27$, 28 d.f., $P < 0.05$) or of an association between size and polygyny (see below).

Since several monogamous species are of small size (such as *Callicebus* spp., *Saguinus* spp.) it is necessary to consider whether the overall relationship between dimorphism and socionomic sex ratio could be the product of that between the former and body weight. To do this, we linearised the relationships and used a partial regression analysis²⁰. This tests whether a dependent variable (in this case, sexual dimorphism) is significantly related to each of two or more independent variables (socionomic sex ratio and body weight) when the effect of the other has been removed. (In the description of results, b_1 refers to the regression coefficient for the first independent variable and b_2 to the second). The analysis showed that sexual dimorphism is significantly related to both variables in the sample as a whole ($b_1 = 0.111$, $t = 2.14$, $P < 0.05$; $b_2 = 0.078$, $t = 3.11$, $P < 0.005$, 39 d.f.) and that 56.3% of the variance in sexual dimorphism is accounted for by the two variables. The relationship to body weight was considerably stronger than that to socionomic sex ratio: standardised partial regression coefficients for sex ratio and body weight are 0.28 and 0.41 respectively. Similar results were obtained when we applied the same analysis to the data for arboreal primates only

Fig. 1 Sexual dimorphism in body weight (weight of male/weight of female) plotted against socionomic sex ratio (females per male). ■, Arboreal; ●, terrestrial.

Fig. 2 Sexual dimorphism in body weight plotted against average of adult male and adult female body weight. ■, Arboreal; ●, terrestrial.

($b_1 = 0.097$, $t = 1.81$, $P < 0.1$; $b_2 = 0.064$, $t = 2.32$, $P < 0.05$, 27 d.f.).

Why should sexual dimorphism in body weight be positively correlated with absolute body weight? There is extensive evidence that this relationship is not confined to primates and occurs in invertebrates²¹, birds^{10,21,22}, rodents (G. Mace, personal communication) and carnivores. It was apparently first recognised by Rensch^{21,23} who attributed it to allometric growth: "Secondary sexual characters of many mammals usually represent structures of positively allometric growth because they usually become more conspicuous during a more advanced period of ontogenetic development (due in mammals to the increasing influence of sex hormones)".

There is, however, no obvious reason for supposing that allometry is inevitable. At least six functional explanations could be involved. It has been suggested that sexual selection for increased size in males may, as a side effect, have led to increased female size thus creating a relationship between dimorphism and average body size²⁴. This seems unlikely because it requires the assumption that increases in male size are more closely paralleled by increases in female size in small animals than in large. Moreover, selection for energetic efficiency probably imposes strict constraints on female size^{9,10,18,25}. Alternatively, it is generally true that large body size is associated with a reduction in the number of competing species^{26,27}. This could relax constraints on increasing male body size imposed by the presence of larger species in neighbouring niches, allowing sexual selection for male competitive ability to produce relatively large increases in male

size. There is evidence that in some birds sexual dimorphism in body size is commonly associated with sex differences in food choice (see above) and that the presence of competing species can constrain intraspecific variance in many characteristics, including size²⁶⁻²⁸. It is also possible that energetic constraints on increasing male body size may be relaxed in larger species since larger body size leads to a decrease in the surface area: volume ratio, metabolic rate and relative nutritional requirements (refs 30-32 and J. Kurland, personal communication) thus making further increases energetically 'cheaper'. Alternatively, where dimorphism permits the sexes to diverge in food choice, selection may favour increased feeding divergence (and thus increased dimorphism) in species which feed on low density food distributed in clumps²² since, in this situation, the effects of feeding competition are strongest. Mammalian species which feed on dispersed and unpredictable food supplies are often of large size^{12,32}. Finally, it is possible that evolutionary factors favouring the reduction of female size may be involved³³. It has been argued that, in fluctuating environments, smaller females may be able to breed at a younger age than larger ones³⁴ and it is conceivable that this pressure might be more acute in large species where the age at first breeding is relatively late, than in small species where it is generally early.

None of these explanations is wholly satisfactory and evidence to support them is almost totally lacking. Until they have been investigated systematically, however, it would be premature to assume that the relationship between body weight and sexual dimorphism is inevitable.

Ultrastructure of the spermatophores of *Siboglinum ekmani* Jägersten (Pogonophora)

THE marine invertebrate phylum Pogonophora has attracted much attention since its discovery in 1914 because of its uncertain phylogenetic position and its unusual biological features, such as the lack of a digestive tract^{1,2}. Little is known of the spermatophores and the mechanism of fertilisation^{1,3}, although it has been suggested that the long filament of the spermatophore serves as a flotation device⁴. Because the expulsion of spermatophores into the sea would involve great wastage of sperm, however, some form of copulation has been said to be likely⁵. Expulsion of spermatophores by the tentacles of the male has been observed in one species³, but even in dense populations of 200 animals per m², which have been reported¹, the tentacles are too short to transfer the spermatophores to the females. Electron microscopy has now revealed that the spermatophoral filament is equipped with numerous electron dense 'threads', composed of tubular elements with a central electron dense core. Apparently the 'threads' which receive their strength from the tubular elements, play an important part as a floating or adhesive apparatus of the released spermatophores.

Several specimens of *Siboglinum ekmani* Jägersten were collected from the Skagerrak during tests of the German research vessel Poseidon (January 1977, 57°50'N, 8°05'E, 537 m deep, 3.4°C, salinity 32.6 ‰). The animals were removed carefully from their tubes using pointed watchmaker's

Fig. 1 Transverse section of sperm duct. Spermatophore containing mature spermatozoa cut at various levels (left), electron-dense threads (right) and parts of the filament (bottom). Phosphate-buffered glutaraldehyde (3.5%) and osmium (2%) fixation. Araldite embedding, uranyl acetate and lead citrate staining ($\times 6,080$).

forceps. Mature males were identified easily by the large numbers of spermatophores within the transparent sperm ducts.

Sections cut at various levels of the sperm ducts show the well known spindle-shaped spermatophores, portions of their coiled filaments and numerous electron-dense threads of unknown function (Fig. 1). These threads are about 0.5 μ m in diameter and several μ m long, their irregular shape preventing exact measurement. High magnifications reveal a new structural element, which I call 'dense core tubuli'. These tubuli constitute the major structural unit of the spermatophore wall as well as the long filament and the electron-dense threads (Fig. 2). The tubuli are embedded in an amorphous ground substance. They have an outside diameter of 150–170 Å, thus being slightly smaller than the microtubules of many plant and animal cells. In contrast to microtubules, they are clearly extracellular. Their length is indeterminate but tubules of several μ m have been

Fig. 2 Cross sections of electron dense thread (left) and spermatophore wall (right) reveal the dense core tubuli ($\times 152,000$).

observed. Occasionally the central core is composed of sub-units which also form a tubular structure. Dense core tubuli are linked in regularly spaced arrangements: 12–180 tubules are longitudinally orientated within the threads. In the spermatophore wall the arrangement resembles dense connective tissue of vertebrates.

Clusters of dense core tubuli also occur between developing male germ cells in the testes. Regularly linked tubuli are attached to groups of mature spermatozoa to mould the envelope of the spermatophores in the proximal region of the sperm ducts. Released spermatophores tend to stick firmly to the tube or trunk of the animal even after fixation, dehydration and embedding. This indicates remarkable adhesive properties. When spermatophores are exposed to seawater, the regular arrangement of the dense core tubuli is gradually lost and the spermatophore wall starts to disintegrate⁶. The filament

Fig. 3 Two stalked vesicles of the spermatophoral filament. Delicate spines project from the surface into the fibrous cover ($\times 30,500$).

uncoils, and at intervals it has areas of radiating stalked vesicles (Fig. 3). Within the sperm ducts these vesicles are smaller, from which I conclude that the filament uncoils through the swelling of the vesicles. They are probably identical with the capitate processes revealed by light microscopy^{3,7}. Fibrous, sticky material covers the surface of the vesicles, reinforced by delicate spines (Fig. 3). The dense threads found in the sperm ducts are also released and frequently appear near the spermatophores in sections. Undoubtedly, the stalked vesicles of the filament and the dense threads form an effective adhesive apparatus and floating device.

My investigation adds further support to the view that the released spermatophores of *Siboglinum* find their way passively without 'some form of copulation' to a receptive female^{1,5}. But further observations are required to elucidate the path of the released spermatozoa to the eggs.

Blood-sucking flies and primate polyspecific associations

PRIMATE polyspecific associations are likely to be an effective means of reducing the number of fly bites individual monkeys receive¹. The probability of acquiring a vector-borne disease, and the severity of that disease increases with the number of fly bites an animal receives^{2–4}. Bait animals placed in groups are known to attract fewer individual mosquitoes per bait individual than are bait animals placed singly^{3,5}. Mean group size of the mangabey, *Cercocebus albigena* is about 13 in Kibale Forest, Uganda, and the mean group size of *Colobus badius* and *Cercopithecus ascanius* are 50 and 35 respectively⁶. Associations of groups of these species are likely to reduce significantly the number of dipteran bites individual monkeys receive^{1,7}. Other explanations proposed for primate polyspecific associations include increased food location abilities, and increased predator detection and avoidance^{8,9}. I report here the correlation of the temporal occurrence of *C. albigena* polyspecific associations with the activity of biting and sucking flies, *C. albigena* feeding and other activities, and the temporal occurrence of attacks by the crowned eagle-hawk (*Stephanoaetus coronatus*) (eagles are the only known predator of these monkeys). The study was carried out in the Kibale Forest, Ngogo Reserve.

On 5 d each month from January to September 1975, I followed a group of *C. albigena* from dawn to dark. Data on mangabey activity and polyspecific associations were recorded during four 5-min periods each hour (0–5, 15–20, 30–35 and 45–50 min). During each 5-min period as many individual *C. albigena* as possible were located, and the predominant activity of each during a 10-s interval was recorded. 'Moving', 'sitting', and 'feeding' are the activity categories used here. The location of each *C. albigena* observed was plotted on a map (4 cm = 100 m) of the study area. To record daily and hourly movements, net group displacements were measured from one 5-min period to the next. The actual distance measured was from the central focus of individuals in one 5-min period, to the central focus of the next. A polyspecific association was defined as the presence of more than one individual of another species within 20 m of the nearest mangabey. Times of eagle attack were recorded as they occurred. Attacks took the form of an eagle flying fast and low through the tree tops and branches, usually through the midst of the mangabey group. Activity of biting and sucking flies was determined using myself as bait. On 4 d I placed myself (naked arms and legs) on a platform 20 m above the forest floor, and remained there from dawn to dark. All flies (mosquitoes and others) biting me were recorded each hour, and when possible I killed all flies actually biting. Data from all days have been aggregated.

The *C. albigena* group took part in polyspecific associations on 43 of the 45 d of observation. Of a total 513 associations, 90.8% involved *C. ascanius*, 22.01% *C. badius*, 5.07% *Colobus guereza*, 1.75% *Papio anubis* and 0.59% *Cercopithecus thoeisti*. There was little interaction between species during the associations. On two occasions juvenile *C. albigena* attempted to join play groups of the other species. Other interactions were confined to adult *C. albigena*, displacing or occasionally chasing *C. ascanius*.

The occurrence of *C. albigena* in polyspecific associations was not equally distributed throughout the day ($\chi^2 = 19.71$, d.f. = 9, $P < 0.05$) (Table 1). There was a significant correlation between the hourly occurrence of polyspecific associations and the hourly activity of biting flies ($r_s = 0.63$, $N = 10$, $P < 0.05$) (Table 1). Because the data on Kibale fly activity are sparse, I also compared the temporal pattern of associations with the timing of mosquito activity in rainforest in Bwamba County, Uganda¹⁰. The correlation is significant ($r_s = 0.66$, $N = 10$, $P < 0.05$) (Fig. 1).

There were no significant correlations between the hourly occurrence of primate polyspecific associations and eagle attacks ($r_s = 0.119$, $N = 10$, $P > 0.05$), mangabey feeding activity ($r_s = 0.08$, $N = 10$, $P > 0.05$), sitting activity ($r_s = -0.08$, $N = 10$, $P > 0.05$), movement activity ($r_s = 0.42$, $N = 10$, $P > 0.05$), and the hourly distance travelled ($r_s = -0.05$, $N = 10$, $P > 0.05$) (Table 1).

Table 1 Polyspecific associations, feeding, moving and sitting activities, hourly distances travelled, eagle attacks and the number of biting flies of a group of mangabeys

Time	Total associations	Feeding observations	Sitting observations	Moving observations	Mean distance travelled (m)	Eagle attacks	Biting flies
0800-0900	57	308	170	200	107	3	12
0900-1000	41	367	123	209	133	1	5
1000-1100	42	410	145	187	100	4	5
1100-1200	35	400	157	196	118	4	1
1200-1300	24	298	178	241	141	1	9
1300-1400	54	364	167	168	95	2	11
1400-1500	36	321	158	218	164	2	11

r_s		0.08	-0.08	0.42	-0.50	0.119	0.63
P		NS	NS	NS	NS	NS	<0.05

The diurnal periodicity found in the occurrence of primate polyspecific associations is in agreement with studies on other African primates¹¹, and previous work on Kibale primates⁸. During the early mornings I noted that several species had frequently slept adjacent to one another. The dawn and dusk peaks in polyspecific associations probably represent the initiation and termination of night-long associations. As the *C. albigena* group slept in 45 different places on 45 different nights, there does not seem to be any shortage of sleeping sites.

These data do not support the possible existence of increased predator surveillance, increased food detection abilities or chance as causal to primate polyspecific associations. Predator detection may well be improved during the associations, but it does not

explain the temporal patterns. Feeding by two or more species in the same tree or in the same area was common, and one species may well use another as an aid in food location. But again, *C. albigena* feeding activities bore no significant relation to the temporal pattern of association. Predation, food and chance seem to do little more than add noise to a pattern that is probably due to another factor.

The importance of the significant correlation between polyspecific associations and biting fly activity is dependent on the importance of dipteran-borne disease to monkeys, and on the probability of polyspecific associations lowering the number of fly bites individuals receive. The size of the primate groups involved, and the published data on effects of number of bait animals suggest that polyspecific associations could easily reduce the number of bites received by individual monkeys. *C. albigena*, *C. ascanius*, and *P. anubis* all suffer from *Hepatoecystis kochi* ('monkey malaria') which is present in Kibale¹². *C. albigena*, and *P. anubis* suffer from *Dirofilaria* sp. and *C. ascanius* have been found with microfilaria¹². All Kibale monkeys suffer from yellow fever, and other arboviruses are probably present¹². Experimental infection of three *C. ascanius* with yellow fever resulted in fevers for 1-3 d, and the death of one due to an 'intercurrent infection'¹². Such effects are likely to have considerable impact on free-living monkeys. A mechanism exists for reducing the number of fly bites received per individual monkey. The temporal pattern of this mechanism correlates with the times of day when it could function to reduce the number of fly bites per individual monkey. Disease organisms using flies as vectors are prevalent among the Kibale monkeys, and seem capable of being a strong selective factor acting to promote primate polyspecific associations.

I thank the Department of Forestry and the National Research Council, Government of Uganda for allowing this study to take place and also my field assistants for their help. The New York Zoological Society, the NIH and the NSF provided financial support.

Physiological correlates of an enzyme polymorphism

ATTEMPTS to demonstrate the action of natural selection at enzyme loci have relied mainly on *in vitro* biochemical techniques to detect differences between allelic forms of the enzymes¹⁻³. It is usually assumed that differences detected in this way will be relevant *in vivo*. The data on human inborn errors of metabolism do not support this view, however; in the majority of cases these are recessive. Heterozygotes, which usually have about 50% normal enzyme activity, rarely show clinical symptoms⁴. As any difference in activity between allozymes is likely to be much smaller, it cannot be assumed that such differences will necessarily be physiologically important. The properties of an enzyme molecule can only be biologically significant to the extent to which they affect the concentrations and flow of intermediates in its metabolic pathways. It was recently shown that changes in the concentration of most enzymes in a pathway at steady state will have little effect on flux^{5,6}. Therefore, to demonstrate that differences in fitness between strains possessing different genotypes at an enzyme locus are caused by that gene substitution, it is necessary not only to show that differences in kinetic parameters can be detected *in vitro*, but also that changes in the activity of the enzyme will affect flux through that pathway. I previously described⁷ significant changes in genotype frequency at a phosphoglucosylase locus in a wild population of field mice (*Apodemus sylvaticus*) which occurred at a time of food shortage and declining population numbers. I report here the results of some *in vivo* experiments on glycogen metabolism in animals of different genotypes at this locus, inducing glycogenolysis by fasting. The results parallel survival data from the wild population and suggest that the genotype of an individual at this locus is of physiological significance and may therefore be subject to natural selection.

The phosphoglucosylase isozyme pattern in field mice is similar to that in man⁷. Of the two loci that are active in erythrocytes, only the faster migrating one (PGM₂) is polymorphic. The two common alleles gave slow (*a*) and fast (*c*) bands on electrophoresis. This enzyme catalyses the interconversion of glucose-1-phosphate and glucose-6-phosphate—a reaction which links the pathways of glycogenolysis and glycolysis. In contracting muscle the flux passes directly from one pathway to the other but when liver glycogen is mobilised it is released primarily as free glucose. This pathway in liver is unusual in that it is short and has a clear beginning and end so that flux can be determined by measuring changes in stored glycogen concentration.

Liver glycogen content, estimated with the anthrone reagent^{8,9}, falls when field mice are fasted overnight. The mean concentration in 28 control animals was 28.9 mg per g wet weight (s.e., 2.41) while in 58 fasted animals it was 13.4 mg per g

(s.e., 2.41; $t_{85} = 5.4$, $P < 0.001$). PGM₂ genotype was known for 16 of the control animals. There was no significant difference between genotypes: eight animals of the *aa* genotype had a mean value of 26.1 mg per g (s.e., 3.8) while an equal number of *ac* animals had a mean of 22.2 mg per g (s.e., 3.7).

Table 1 shows the relationship between liver glycogen level and PGM₂ genotype in 48 fasted animals. The mean for the *aa* genotype is significantly lower than the combined mean for the other two groups ($t_{46} = 3.32$, $P < 0.01$). These data show a correlation between liver glycogen metabolism and PGM₂ genotype which is revealed by fasting, although genetic studies would be required to establish the causal nature of this relationship.

Table 2 shows recapture rates for each PGM₂ genotype in a natural population of *A. sylvaticus* at a time of high density, restricted food supply and falling population numbers⁷. There are significant differences in the proportion recaptured for the different genotypes and, as in Table 1, the heterozygotes give similar results to the *cc* homozygotes. Such data give a minimum estimate of survival rates¹⁰. Although errors in these estimates could arise from genetically non-uniform dispersal, they are unlikely to be large in this case as dispersal is uncommon in declining populations¹¹. The differences between genotypes in physiological responses to fasting may therefore lead to differences in survival rates at a time of food shortage.

Table 2 Recapture rate of field mice according to PGM₂ genotype

PGM ₂ genotype	<i>aa</i>	<i>ac</i>	<i>cc</i>
Total caught	22	36	18
Total recaptured	11	7	2
Proportion	0.50	0.19	0.11

Data from a natural population at Charnwood (Leicestershire, UK) giving the minimum survival rate of animals first caught in October 1974. The population was studied for 2 yr by mark-recapture trapping and gel electrophoresis⁷ and this sample represents a single cohort of non-reproductive animals. $\chi^2 = 7.32$, $P < 0.01$.

The impact of genotype at the PGM₂ locus on liver glycogen metabolism is unexpected as this locus provides less than 10% of total PGM activity in human liver¹¹. These results indicate that the two major PGM loci may have different roles *in vivo*; they have already been shown to differ in kinetic properties¹². This view is supported by several studies on the fate of labelled glucose and glucose phosphates *in vivo*¹³⁻¹⁵, which suggest that there may be two pools of glucose-6-phosphate in both liver and muscle, one of which is accessible to exogenous glucose phosphates and is involved in glycolysis while the other, from which glycogen is synthesised, is accessible only to glucose. Each of the two major PGM enzymes may be associated with only one of these glucose-6-phosphate pools, with the PGM₂ enzyme being the more important in glycogen mobilisation.

These results make it possible to visualise a physiological mechanism whereby *aa* animals are more fit than are *ac* and *cc* ones when food supply is restricted. If a higher rate of mobilisation of glycogen reserves is reflected in a higher potential for activity, *aa* individuals will have a competitive advantage when food reserves are few and widely scattered.

Considerable effort has been expended in attempts to demonstrate a selective basis for enzyme polymorphisms by means of *in vitro* biochemical studies¹⁶ although *in vitro* differences may have little physiological importance. The results of the *in vivo* experiments described here suggest that this approach may prove more rewarding.

I thank Dr J. S. Jones for discussions, Drs G. Bulfield and C. H. Langley for criticism of the manuscript and Dr R. Semeonoff for supervision. The project was supported by an SRC Research Studentship.

Table 1 Glycogen content of liver in fasted *A. sylvaticus* according to PGM₂ genotype

Genotype	<i>aa</i>	<i>ac</i>	<i>cc</i>
Mean	6.3	16.5	15.2
s.e.	1.66	4.02	2.25
N	14	18	16

Values are in mg per g wet weight. Electrophoretic methods were as described previously⁷. The genetic background of the experimental animals was standardised by taking F₁ offspring from crosses between two lines, both of which were segregating for the *a* and *c* alleles at the PGM₂ locus. Thus, all the experimental homozygotes had received one allele from each line. Food, normally freely available, was removed from the cages of fasted animals at the start of their night period. All animals were killed 15–16 h later. Liver glycogen was estimated with the anthrone reagent⁸ using sodium sulphate as a coprecipitant⁹. The recovery rate of a glycogen standard with this technique was 92% at an initial concentration of 5%. $P < 0.01$; $t_{46} = 3.32$.

Activated macrophages induce vascular proliferation

MICROVASCULAR proliferation is essential to many biological processes, such as wound healing, but the mechanisms underlying this vascular response are poorly understood¹. Neovascularisation can be induced by extracts from various cell types, including malignant solid tumour cells², normal and viral-transformed (SV40) BALB/c 3T3 cells, and diploid human embryonic lung fibroblasts³, and neutrophils⁴. Extracts of mouse salivary gland⁵ and skin⁶ have been reported to induce vascular growth, but the relevance of these observations to the vascular proliferation that occurs in wound healing and chronic inflammation is unclear. Neovascularisation is also an important component of immunological reactions. Sidky and Auerbach reported increased vessel density in the skin during graft-versus-host reactions and attributed it to the lymphocyte⁷. Herman and associates⁸ and Anderson *et al.*⁹ found an increase in capillary density, and extensive proliferation of postcapillary venular endothelium, respectively, in lymph nodes undergoing strong immunological reactions. We have shown significant endothelial proliferation in delayed hypersensitivity reactions in the skin of guinea pigs at the time of maximal mononuclear cell infiltration¹⁰ and so we have investigated whether macrophages, an important component of immunological and non-immunological inflammatory reactions, might be involved in this vascular response. We report here that macrophages activated *in vivo* and *in vitro*, and media conditioned by these cells, induce vascular proliferation in the guinea pig cornea.

Neovascularisation was assayed in the normally avascular cornea of the guinea pig eye by introducing either cells or media into the stroma and observing the growth of vascular sprouts from the limbus into the cornea. The macrophages were obtained from the peritoneal cavities of untreated guinea pigs, or from guinea pigs or mice that had previously been injected with paraffin oil or thioglycollate, respectively. We have used the terms "non-activated" and "activated" to refer to macrophages from untreated or injected animals, respectively. The activated macrophages were richer in dense phase vacuoles and in pinocytotic vesicles. Macrophages (5×10^5) were injected into the corneal stroma 1.5 mm from the limbus in $10 \mu\text{l}$ of medium 199 (Table 1). Media conditioned by incubation with macrophages *in vitro* (legend to Table 2) were incorporated into Hydron (a polymer of hydroxyethylmethacrylate) as described by Langer and Folkman¹¹, and a 5- μl pellet was implanted in an aseptically created pocket in the corneal stroma¹². This polymer was used because it is non-inflammatory and permits a prolonged release of incorporated compounds¹¹. Corneas were examined daily with a slit-lamp stereomicroscope ($10-40\times$ magnification) for evidence of neovascularisation. After 7 d, just before killing, the animals were perfused intra-arterially with colloidal carbon, which filled the corneal blood vessels and provided a permanent record of the individual vascular response.

Excised corneas were fixed in buffered neutral formalin, flattened, photographed, and then processed for histological examination. A positive neovascular response was recorded when a dense brushwork of new capillary sprouts and hairpin loops grew from the adjacent limbal plexus, in a directional fashion towards the depot of test materials (Fig. 1a and b). When observed *in vivo*, proliferating capillaries were seen to grow $0.1-0.2 \text{ mm d}^{-1}$ and they underwent extensive branching as the response developed. Corneas with positive vascular responses did not become oedematous and histologically showed negligible infiltration by polymorphonuclear leukocytes. Responses were recorded as negative

Fig. 1 Carbon-perfused vessels in Hartley albino guinea pig corneas 7 d after injection of macrophages or implantation of Hydron polymer. *a*, Positive neovascular response induced by homologous *in vivo*-activated (paraffin oil) peritoneal macrophages. Note directional ingrowth of small blood vessels from the limbal plexus adjacent to the injection site (arrows), and the normal vascular pattern around the remainder of the corneal circumference (whole mount preparation). *b*, Higher power view of positive response. The dense neovascular plexus consists of numerous small sprouts and dilated, tortuous loops, which have penetrated the corneal stroma in several planes. *c*, Typical negative response in test cornea implanted with Hydron plus unconditioned RPMI 1640 medium. Note the apparently normal limbal vessel pattern and the absence of both hairpin loops and sprouts (same magnification as *b*).

†Inducing agents (paraffin oil, thioglycollate, peptone); collection media (M199); culture medium (RPMI 1640 \pm 5% foetal calf serum).

‡Resident peritoneal macrophages from Hartley albino guinea pigs and BALB/c mice were obtained from normal non-stimulated animals following lavage with serum-free medium 199 (M199).

§Homologous activated macrophages were obtained from peritoneal exudates in Hartley albino guinea pigs 3 d after an intraperitoneal injection of 30 ml of sterile paraffin oil. Whole exudates suspended in M199 were layered over Lymphocyte-Separation Media (Litton Bionetics) to remove contaminating red blood cells and granulocytes, washed twice and resuspended in M199 for intracorneal injection. These preparations were 85–95% viable (Trypan blue exclusion) and consisted of 85–90% macrophages, <15% lymphocytes, <5% granulocytes, <1% other cells.

¶In four Hartley albino guinea pigs, paraffin oil-induced peritoneal macrophages obtained from individual guinea pigs were tested in their own corneas.

||Paraffin oil-activated macrophages obtained from inbred (Strain II) guinea pigs were injected in the cornea of guinea pigs of the same strain.

**Activated macrophages obtained from BALB/c mice 3 d after intraperitoneal injection of 1 ml of 3% thioglycollate were collected, processed in the same manner as guinea pig exudates and injected in Hartley albino guinea pig corneas.

†† 4×10^6 cells in 1 ml RPMI 1640 \pm 5% foetal calf serum were plated in 35×10 mm Falcon plastic dishes and incubated at 37 °C with and without sterile latex particles (Dow Chemical, 1.09 μ m diameter, 50 beads per cell)¹⁶. After incubation for 1 h, non-adherent cells and latex were removed by washing, and adherent macrophages were detached by a 10-min treatment with 10 mM lidocaine, washed, suspended in RPMI 1640 and injected into test corneas.

when no growth, or only occasional capillary sprouts or hairpin loops, with no evidence of sustained directional growth were observed (Fig. 1c).

Tables 1 and 2 summarise the cumulative results of cells and media tested. Control materials (paraffin oil, thioglycollate, peptone; collection media, culture media incubated without cells; pellets of Hydron or Hydron and control media) showed activity in 3 out of 51 corneas tested (6%). Resident non-activated macrophages showed activity in 2 out of 24 corneas (8%). In contrast, *in vivo* activated macrophages (regardless of their source) induced a neovascular response in 41 out of 55 corneas tested (75%). In addition, macrophages stimulated *in vitro* by latex ingestion were more active (5 of 7 corneas) than unchallenged macrophages (1 of 4 corneas). Finally, incorporation of conditioned media from cultures of heterologous activated macrophages in Hydron pellets induced neovascularisation in 15 of 23 corneas (65%).

Our results demonstrate that macrophages can induce microvascular proliferation *in vivo* and they also point to some of the possible mechanisms for the reaction. First, from histological studies it seemed that the microvascular responses were not associated with an acute inflammatory response¹³. This was in contrast to other studies in which neovascularisation by macrophages was accompanied by acute inflammation¹⁴. Such a response complicates the issue of deciding which cell is

ultimately responsible for the reaction. Furthermore, in preliminary studies, we have been unable to produce corneal neovascularisation by implanting neutrophils or activated lymphocytes. Second, the neovascularisation could not be attributed solely to an immunological reaction since it was produced in a completely syngeneic cell system. These two points lead us to believe that the response is directly attributable to the macrophage, although some subtle interaction with other cell types cannot be strictly excluded. It is of interest that the responses to macrophages required their activation; namely, the macrophages either had to be obtained from peritoneal cavities following inflammation, or the cells had to be stimulated to phagocytose latex particles *in vitro*. There is ample evidence for increased macrophage function following various modes of stimulation¹⁵. Indeed, changes in phagocytic properties (for example, in secretion, in lysosomal contents) take place following stimulation of macrophages by various means. In the context of the possible *in vivo* significance of the phenomenon, it seems that the neovascularising properties of macrophages are inducible rather than constitutive. Finally, the results showing that macrophage-conditioned media contained an active material strongly suggests that the mechanisms responsible for the phenomenon may be by way of secretion of an active molecule. Macrophages can secrete a variety of macromolecules^{16–19} and characterisation of the active material is now in progress. Our

Table 2 Corneal neovascularisation induced by macrophage-conditioned media

Test material	Total no. of corneas tested	No. of negative	No. of positive	% Positive

Hydron and control media†	12	11	1	8
Hydron carrier	15	13	2	13

*Macrophage-conditioned media were prepared by culturing peptone-induced BALB/c mouse peritoneal macrophages for 24 h in serum-free RPMI 1640 media¹⁶. After centrifugation, samples were dialysed for 72 h against RPMI 1640 to remove low molecular weight inhibitors of DNA and protein synthesis and concentrated on an Amicon UM05 filter. Conditioned medium (2.5 μ l; 0.5×10^6 – 2.5×10^6 cell equivalents) were then combined with an equal volume of sterile Hydron casting solution (prepared by dissolving the polymer in absolute alcohol at 37 °C)¹¹, and allowed to dry overnight before implantation.

†RPMI 1640 medium, incubated without cells and processed as described above.

observations therefore suggest that, among its diverse functions in the chronic inflammatory response, the macrophage may mediate microvascular proliferation.

We thank Dr S. Schlossman for his gift of Strain II guinea pigs, and Drs R. Langer and J. Folkman for assistance with the Hydron technique. This work was supported by a grant from the USPHS. M.A.G. is the recipient of an established investigatorship from the American Heart Association.

Human virus-infected target cells lacking HLA antigens resist specific T-lymphocyte cytotoxicity

PRODUCTS of the major histocompatibility complex (MHC) are important as target structures in T lymphocyte-mediated cytotoxicity. In mice, virus (or hapten)-sensitized T cells are cytotoxic for specific virus-infected (or hapten-modified) target cells exclusively when syngeneic or at least identical for either the K or D region of the MHC¹⁻⁵. These findings led to the 'altered-self' hypothesis⁶ which assumed that cytotoxic T cells do not recognise specific viral antigens, but rather a modification of histocompatibility antigens induced by the viral infection. One prediction of this theory was that murine cells expressing viral antigens but lacking H-2 determinants would be resistant to T cell-mediated lysis. Indeed, this fact was established recently by Zinkernagel and Oldstone using murine F 9 teratoma cells⁷. There is still no evidence for the involvement of HLA antigens in the process of immune killing of virus-infected target cells by human T lymphocytes. But, Svedmyr and Jondal have shown that peripheral T cells from patients with infectious mononucleosis (IM)—and not from normal donors—killed specifically Epstein-Barr virus (EBV) genome-carrying B lymphoblastoid cell lines⁸ and Burkitt's lymphoma cells⁹. By contrast, these T cells were devoid of any cytotoxic activity against EBV negative cell lines. Similar data were obtained by other workers^{10,11}. Thus, peripheral T cells from patients with infectious mononucleosis seemed to be sensitised to viral coded determinants, and could presumably be used in a model to study T-lymphocyte killing of virus-infected cells in human. If, in man as well as mouse, the MHC is directly involved in the target structure recognised by virus-sensitized cytolytic T lymphocytes, HLA-lacking target cells

should be resistant to immune T-cell killing. We report here that Daudi cells, originating from a human Burkitt's lymphoma line and lacking HLA products¹²⁻¹⁴, are resistant to lysis by EBV-sensitized peripheral T lymphocytes from patients with infectious mononucleosis.

The experiments involved a ⁵¹Cr release assay according to Cerottini and Brunner¹⁵ with minor modifications. Targets were cells from several B-lymphoblastoid lines and effectors were peripheral T lymphocytes from patients with infectious mononucleosis. The EBV genome-carrying lines used were T-51 (ref. 16), 8866 (ref. 17) and Daudi, and the EBV-negative line was Ramos¹⁸. All lines were maintained in our laboratory. Effector cells were purified from the blood of six patients with infectious mononucleosis, as assessed by a positive Paul Bunnell-Davidson test. Peripheral lymphocytes were isolated on Ficoll-Hypaque gradients. As unpurified peripheral blood lymphocytes exerted nonspecific killing on cell lines⁹, further purification of T cells was required. This was achieved by removal of B cells either by EAC rosetting or by use of a cytotoxic anti-B antiserum¹⁹. These processes yielded 99% pure T lymphocytes as assessed by E rosette formation.

Peripheral T lymphocytes from patients with infectious mononucleosis were cytotoxic for cells from the two HLA-positive EBV genome-carrying lines T-51 and 8866, whereas they were unable to kill cells from the HLA-positive EBV genome-negative line Ramos (Fig. 1). These results are in complete agreement with the data of Svedmyr and Jondal⁸. Strikingly, Daudi cells, though containing EBV genome, were resistant to lysis by these EBV-sensitized T cells. The human cell line Daudi lacks HLA products as assessed by the absence

Fig. 1 Cytotoxicity of T lymphocytes from a patient with infectious mononucleosis towards target cell lines. Cytotoxicity tests were performed in U-shaped microtitre plates in a total volume of 0.2 ml RPMI 1640 medium supplemented with antibodies and 10% human AB serum (previously tested for absence of any cytotoxic activity). 2.5×10^4 labelled target cells and 1.25×10^6 or 2.5×10^6 effector cells were mixed (effector:target ratio of 50:1 or 100:1). Cultures were set up in triplicate. After 12-14 h of incubation at 37 °C in 5% CO₂ atmosphere, the supernatant of each culture was collected and ⁵¹Cr release was measured using a γ counter (Intertechnique). Simultaneously, spontaneous release in the presence of saponin was measured. Specific lysis was expressed according to the formula

$$\frac{\text{Experimental release} - \text{Spontaneous release}}{\text{Total release} - \text{Spontaneous release}} \times 100$$

a, Daudi cell line; no HLA products, EBV genome positive. b, Ramos cells, HLA phenotype 3-5-X-Y, negative for EBV genome. c, T-51 cells, HLA phenotype 1-2-8-W27, EBV genome positive. d, 8866 cells; HLA phenotype 2-3-7; EBV genome positive.

of reactivity with anti-HLA antisera tested by cytotoxicity, absorption, immunofluorescence and immunoprecipitation¹²⁻¹⁴. Daudi cells express EBV-coded determinants, however, as shown by reactivity with relevant antibodies (anti-EBNA and MA)^{20,21}. Finally, Daudi cells are susceptible to antibody-mediated immune killing, since they could be lysed in ADCC assay using anti-EBV sera and normal lymphocytes²¹ and in complement-dependant cytotoxicity assay using different anti-B sera¹³. This is also established by our own data as shown in Table 1. Daudi cells were lysed by rabbit anti-human lymphocyte serum in presence of complement and not by anti-HLA serum. Also, ADCC was positive using anti-lymphocyte and anti-B cell sera, but negative using anti-HLA serum. According to results from murine models, it is tempting to assume that the resistance to lysis by EBV-sensitised T lymphocytes exhibited by Daudi cells is due to their lack of HLA products.

Table 1 Susceptibility of Daudi cells to lysis by antibodies

Target cell treated with*	% of specific cytotoxicity Antibody- and complement- dependent*	Antibody- dependent† cellular cytotoxicity (ADCC)
Normal AB serum	0.5	—
Normal rabbit serum††	0	2.9±0.6
Anti-HLA serum (Eluate from platelets)	0.5	8.5±1.2
Rabbit anti-human lymphocyte serum†	0	20.6±1.5
Human anti-B cell serum (Eluate from Daudi cells)	ND	26.0±0.9
Normal AB serum + guinea pig complement	1.8	—
Normal rabbit serum + guinea pig complement	2	—
Anti-HLA serum + guinea pig complement	1.3	—
Rabbit anti-lymphocyte serum + guinea pig complement	96.4±1.8	—

* 5×10^4 ⁵¹Cr-labelled Daudi cells were incubated with 150 µl of sera (1/30 dilution) for 30 min at 37 °C, then 100 µl of guinea pig serum (1/2 dilution) used as complement for 1 h. Cells were spun down from aliquots of cell supernatants and c.p.m. counted. % of specific cytotoxicity was calculated according to the formula

$$\frac{\text{c.p.m. total release} - \text{c.p.m. spontaneous release}}{\text{c.p.m. experimental release} - \text{c.p.m. spontaneous release}}$$

† 5×10^4 ⁵¹Cr-labelled Daudi cells were incubated with the sera for 30 min at 37 °C before addition of 10^6 human lymphocytes separated by gradient of Ficoll-Triosil. Final dilution of the sera was 1/500. After 16 h, percentage of cytotoxicity was calculated as above and results expressed as compared with the effect of AB sera (% of ⁵¹Cr-release in presence of experimental serum - % of ⁵¹Cr-release in presence of AB serum).

†† Absorbed on mouse cells.

This would imply that the HLA antigens are directly involved in the structure recognised by cytotoxic T lymphocytes at the surface of virus-infected target cells.

Analysis of the results of Svedmyr and Jondal⁸ shows a wide variability of the range of specific killing of each effector lymphocyte population towards different cell lines. This observation might be explained by a necessary requirement of HLA identity between target cells and effector cells, as suggested by murine models.

T lymphocytes from patients 3 and 4 did indeed exert higher specific killing for 8866 than for T-51 cells, while T lymphocytes from patient 6 were more cytotoxic for T-51 target (Table 2). This excludes a higher susceptibility to lysis of one cell line as compared with the other and may evoke a requirement of some HLA compatibility between effectors and targets. It should be noted, however, that T cells from patients 5 (HLA phenotype A.9 A.10 BW.35 BW.38) and 6 (A.9 A.19.2 B.14) were cytotoxic towards target cells with which they shared no HLA antigens.

Table 2 Cytotoxicity of T cells from individual patient with infectious mononucleosis cell lines

Patient	Target cells	Effector- target ratio	% ⁵¹ Cr release*	% specific lysis†
I	Daudi	—	32.1±2.15	—
		10:1	28.6±1.8	-5.1±2.7

* %⁵¹Cr release (±s.e.m.) calculated according to the formula

$$\frac{\text{c.p.m. experimental release}}{\text{c.p.m. total release}} \times 100$$

† Values given ±s.e.m. methodology and specific lysis determination as in Fig. 1 legend.

Therefore in man, the histocompatibility identity did not seem to be as strongly required as in murine models.

But it is well established that series of irrelevant specificities can be detected on cell lines by usual HLA serotyping. For instance, T-51 cells additionally reacted with sera directed against HLA 10 and 21 and 8866 with anti-HLA 1-11-28-19-2-27-5-29-35-21 antisera. These irrelevant reactions could be due to alloantibodies directed to Ia-like B-cell antigens. It might be postulated that the expression of HLA antigens at the surface of cell lines allows a high degree of cross reactivity with alloantisera²², or that virus-infected cell possibly express new HLA specificities, as suggested in the mouse²³. If the latter were so, this would explain why cell lines would not apparently be submitted to strong allogeneic restriction when used as target cells. It remains possible that much higher specific killing could be observed if the target cells were autologous EBV-infected B lymphocytes from the infectious mononucleosis patient whose T cells are used as effectors. This possibility is presently under investigation.

But, regardless of the apparent lack of allogeneic restriction in this model, the fact that Daudi cells are resistant to lysis by EBV-sensitised T cells is the first evidence to suggest direct HLA involvement in anti-viral T-cell killing in man.

We thank Mrs Colette Chereau, Maryvonne Guillard, Marielle Dutheil and Yvonne Thies for technical assistance. This work was supported by grants from Inserm and Institut Gustave-Roussy, Villejuif, France.

Note added in proof: After submission of our paper, another example of implication of HLA in the target structure of T-cell killing was published (Goulmy, E., Termijtelen, A., Bradley, B. A. and van Rood, J. J. *Nature* **266**, 544-546, 1977) concerning the response to the H-4 antigens. In this case the authors found an allogeneic restriction to HLA-2.

Evidence for an H-2/viral protein complex on the cell surface as the basis for the H-2 restriction of cytotoxicity

CYTOTOXIC T lymphocytes generated in mice by immunisation with syngeneic Friend virus (FV)-induced tumour cells show H-2 restriction, that is, their cytotoxicity is specific not only for FV-associated antigenic determinants expressed on the surfaces of potential target cells but also for products of genes associated with the major histocompatibility complex, H-2 (ref. 1). We report here the results of studies concerning the role of molecules governed by genes in the K and D regions of the H-2 complex in the stimulation of FV-specific immune responses. Studies in other viral systems have shown that H-2-restricted T-cell

killing can be associated with either K or D region determinants, that is, cytotoxic T cells from virus-infected mice will kill virus-infected target cells which share either the K or D region with the infected strain². Our studies, however, indicate that in the FV system there is a selective participation of H-2 determinants in virus-specific killing by cytotoxic T cells: BALB.B mice immunised with cultured, syngeneic FV-induced tumour cells produce T cells with a cytotoxicity for other FV-induced tumour cells which depends only on identity at the H-2D (and not the H-2K) region of the H-2^b haplotype. This H-2D^b restriction in FV-specific cytotoxicity correlates with previous observations concerning: (1) partial co-capping of H-2D^b and not H-2K^b specificities following treatment with anti-FV antiserum³; (2) selective incorporation of H-2D^b and not H-2K^b specificities into mature FV particles⁴; and with our present observation of (3) blocking of T-cell cytotoxicity by anti-H-2D^b and not anti-H-2K^b antisera. We suggest that the basis for this correlation is the formation of H-2D^b/viral protein complexes on the surfaces of FV-infected cells, forming an 'altered self' molecule recognised by cytotoxic T cells as previously proposed for the mechanism of H-2 restriction⁵.

Mice for these studies were of the BALB/c strain (H-2^d) or of congenic strains differing at the H-2 complex: BALB.B (H-2^b from C57BL/10) or BALB.G (H-2^g, a recombinant haplotype originating from an H-2^b/H-2^d heterozygote, from HTG/Go). Cultured FV-induced tumour cell lines derived from mice of these strains were of the HFL series⁶: HFL/b from BALB.B, HFL/d from BALB/c, and HFL/g from BALB.G. Cells of each of these lines express both the FV-induced FMR cell-surface antigen and the virus envelope antigens associated with the gp70 protein of FV.

BALB/c, BALB.B and BALB.G mice were immunised by intraperitoneal inoculation of syngeneic HFL tumour cells. Peritoneal exudate cells (PEC) taken on day 5 after the second or third inoculation were assayed for lymphocyte-mediated cytotoxicity (LMC) by the method of Burke *et al.*⁷, using ⁵¹Cr-labelled HFL tumour cells as targets. Controls for the sensitivity of the LMC reaction to pretreatment with anti-Thy-1.2 antiserum and complement were included in most experiments and demonstrated that the killing was attributable to T cells.

Table 1 H-2 restriction of T-cell cytotoxicity

Mice immunised*	H-2 haplotype	Syngeneic immunising cells	Target cell cytotoxicity (% ⁵¹ Cr release)			
			HFL/b	HFL/g	HFL/d	HFL/k
BALB.B	b b b b	HFL/b	18	15	0	0
BALB.G	d d d b	HFL/g	20	37	1	0
BALB/c	d d d d	HFL/d	0	0	0	0

In the LMC, 2.5×10^6 immune PEC in 1 ml and 5×10^4 ⁵¹Cr-labelled tumour cells in 0.1 ml (PEC-target cell ratio, 50:1) were mixed and incubated at 37 °C in 5% CO₂ atmosphere for 6 h. The cells were suspended in Medium 199 plus 20% foetal calf serum. Specific release of radioactivity into supernatant was compared with that from tumour cells alone frozen and thawed four times.

*PEC were collected at previously determined peaks of activity, 5 d after the second or third immunisation.

One criterion used to define the extent of H-2 identity with target cells which would permit the T cells to exert their cytotoxicity was direct cross reactivity in the LMC assay (Table 1). The marked cross reactivity of BALB.B anti-HFL/b and BALB.G anti-HFL/g PEC indicated that H-2D^b identity was sufficient to permit killing to occur. Whether H-2K^b identity was also sufficient could not be tested by this technique, since no target cell was available which shared this genotype but differed in the H-2D region. The observation that BALB.G anti-HFL/g PEC were ineffective against HFL/d tumour cell targets suggested that H-2K^d, H-2I^d and H-2S^d region identity was not sufficient to permit killing.

Another criterion used to elucidate the precise requirements for *H-2* identity between immunising and target cells, was the capacity of high concentrations of specific anti-*H-2* antisera added to the reaction mixture to block T-cell killing of syngeneic target cells⁸. Accordingly, we tested the capacity of antisera specific for either *H-2K^b* or *H-2D^b* antigenic determinants to inhibit the cytotoxicity of BALB.B anti-HFL/b PEC for HFL/b target cells. The results (Fig. 1) showed that anti-*H-2D^b* antibodies were effective in blocking the reaction whereas anti-*H-2K^b* antibodies showed no greater inhibitory effect than did irrelevant anti-*H-2K^k* antibodies. Preliminary attempts to detect blocking in this same reaction by antibodies to specific FV proteins met with little success; of the various antisera tested, only one of three available pools of goat anti-gp70 antiserum demonstrated significant inhibitory activity (data not shown).

Fig. 1 Lysis of HFL/b target cells by peritoneal exudate cells (PEC) from BALB.B mice immunised with HFL/b tumour cells. PEC (2.5×10^6) in 0.2 ml and 5×10^4 ^{51}Cr -labelled tumour cells in 0.1 ml were mixed together with 0.1 ml of diluted anti-*H-2* antiserum and assayed for lymphocyte-mediated cytotoxicity as noted in Table 1. Antisera used were: \circ , anti-*H-2D^b* (BALB/c anti-BALB.G normal spleen cells); \triangle , anti-*H-2K^b* [(A \times BALB.G) F_1 anti-BALB.B normal spleen cells]; \square , anti-*H-2K^k* (BALB.B anti-BALB.K normal spleen cells).

These experiments indicate that T-cell recognition of foreign antigenic determinants on FV-induced *H-2^b* and *H-2^d* tumour cells involved specificities associated with both the *H-2D^b* molecule and a virus molecule, perhaps gp70. The *H-2K^b* and *H-2K^d* molecules did not seem to be involved in this recognition, and no assessment of the possible involvement of the *H-2D^d* molecule could be made, since cytotoxic activity has never been detected in any of several experiments with PEC from BALB/c mice immunised with HFL/d tumour cells. Our findings correlate with those of recent studies in which disrupted FV particles collected from the serum of infected (BALB/c \times BALB.B) F_1 mice (*H-2^b/H-2^d*) were examined for *H-2* antigen content and found to have incorporated *H-2D^b* but not *H-2K^b*, *H-2D^d* or *H-2K^d* determinants⁴. These two sets of experiments strongly imply that a physical association between a viral molecule and the *H-2D^b* molecule occurs on cell surfaces which is based on an affinity between the two molecules which does not exist between the viral molecule and the *H-2K^b*, *H-2D^d* or *H-2K^d* molecules.

Two further sets of experiments provide an indication that this molecular association may be of importance *in vivo*. First, the rejection of grafts of cultured, syngeneic HFL cells was correlated with the presence of *H-2D^b* molecules (Table 2). All BALB.B mice and 76% of BALB.G mice rejected HFL/b and HFL/g cell grafts, respectively, whereas only 8% of BALB/c mice rejected HFL/d cell grafts.

Second, we attempted to demonstrate that the antigenic specificities of cultured HFL tumour cells recognised by immune T cells were the same as those of primary FV-infected cells *in vivo* by carrying out adoptive transfer experiments (Table 3). Spleen

Table 2 Survival of mice challenged with syngeneic tumour cells

Recipient mice*	Tumour cells	Cell dose	No. survivors/no. inoculated
BALB.B	HFL/b	5×10^6	57/57
BALB.G	HFL/g	5×10^6	16/21
BALB/c	HFL/d	5×10^6	1/12
		5×10^5	2/14

*Mice were inoculated i.p. with syngeneic tumour cells and observed for 8 weeks.

cells from BALB.B and BALB.G donor mice which had rejected syngeneic HFL cell grafts were injected into irradiated (350 R) non-immune syngeneic recipient mice which then received a high dose of FV. Control recipients of non-immune spleen cells developed the pronounced splenomegaly characteristic of the FV disease, whereas recipients of immune spleen cells showed no splenomegaly. Pretreatment of the immune donor spleen cells with anti-Thy-1.2 antiserum and complement abolished their capacity to transfer immunity to the disease.

Table 3 Adoptive transfer of immunity to FV by syngeneic T cells from mice immunised with syngeneic HFL tumour cells

Irradiated recipients*	Mean spleen weights \pm s.d. (g)		
	A†	B	C
BALB.B	0.15 ± 0.01	2.31 ± 0.27	2.33 ± 0.07
BALB.G	0.10 ± 0.01	1.41 ± 0.21	

*Recipient mice were irradiated (350 R) and inoculated with 1.5×10^7 syngeneic spleen cells i.v.; 24 h later the mice received 3,000 FFU of FV i.v. Spleen weights were determined after 30 d or earlier if mice appeared moribund. Each group included 3–5 mice.

†Group A received immune syngeneic spleen cells pretreated with normal mouse serum and complement; group B received immune syngeneic spleen cells pretreated with anti-Thy-1.2 serum plus complement; group C received syngeneic spleen cells from unimmunised mice.

FV-infected cells which express the *H-2^b* or *H-2^d* but not the *H-2^k* haplotypes show cross-reacting virus-associated antigenic specificities capable of eliciting a cytotoxic T-cell response directed against specificities associated with the *H-2D^b* molecule. This immunogenicity seems to be the result primarily of the formation on the cell surface of an *H-2D^b*/viral molecule complex, but the capacity to form such a complex is not, in general, a property of other *H-2D* or of *H-2K* molecules. It seems likely that this phenomenon is, at least in part, the basis of the observation⁹ that *H-2* type is a major determinant of susceptibility or resistance to viral leukaemogenesis in mice.

This work was supported by a contract with the Virus-Cancer Program and by a grant, both from the National Cancer Institute. K.J.B. was supported by a training grant from the National Cancer Institute. We acknowledge the gift of some of the anti-MuLV protein antisera used from Drs M. Strand and J. T. August.

Effect of protease inhibitors and substrates on deoxycorticosterone binding to its receptor in dog MDCK kidney cells

THE dog kidney MDCK cell line contains a protein in its cytosol that specifically binds deoxycorticosterone (DOC) and can concentrate DOC in its nuclei. A Scatchard analysis of ^3H -DOC binding shows that the K_d is about 8×10^{-8} M (refs 1, 2). We describe here a study of the effects of various protease inhibitors on DOC binding to its receptors. The DOC receptor in MDCK cells may contain a specific structure which recognises protease inhibitors.

The protease inhibitors, phenylmethyl sulphonylfluoride³ (PMSF), tosyl-lysine chloromethyl ketone⁴ (TLCK) and tosylamide-phenylethyl-chloromethyl ketone⁵ (TPCK) eliminate specific ^3H -DOC binding activity in the MDCK cytosol. This occurs both when these compounds are present in the homogenising medium and when added to the 104,000g cytosol just before ^3H -DOC. The elimination of ^3H -DOC binding could be due to these protease inhibitors either interacting with the DOC receptor or preventing a proteolytic process necessary for activation of pro-receptor for DOC. To distinguish between these possibilities, we incubated the 104,000g cytosol with 3×10^{-8} M ^3H -DOC for 2.5 h at 0 °C. By this time, equilibrium binding of the ^3H -DOC has been achieved. Then a 1,000-fold molar excess of nonradioactive DOC, 1 mM PMSF, 1 mM TLCK, or 0.5 mM TPCK was added to aliquots of the cytosol. In 1 h the three protease inhibitors eliminated specific ^3H -DOC binding; whereas the binding of ^3H -DOC by the untreated cytosol did not change (Table 1). We therefore conclude that these protease

Table 1 Effect of protease inhibitors on ^3H -DOC binding in MDCK cell cytosol

Sample	Bound ^3H -DOC (c.p.m. per mg protein)*
^3H -DOC (3×10^{-8} M) 2.5 h incubation	220,300
^3H -DOC (3×10^{-8} M) + DOC (3×10^{-5} M) 2.5 h incubation	19,300
^3H -DOC (3×10^{-8} M) 3.5 h incubation	214,900
^3H -DOC (3×10^{-8} M) + DOC (3×10^{-5} M) 3.5 h incubation	19,900
^3H -DOC (3×10^{-8} M) 2.5 h incubation, then	
PMSF (1 mM) 1 h	21,600
TLCK (1 mM) 1 h	22,000
TPCK (0.5 mM) 1 h	20,000
DOC (3×10^{-5} M) 1 h	19,800

MDCK cells were cultured in Dulbecco-Vogt modified Eagles medium with 10% foetal calf serum on 100-mm Falcon tissue culture dishes. Two days after cell growth had stopped, the cells were washed once with cold phosphate-buffered saline and once with the homogenising solution, 10 mM Tris pH 7.4 + 2 mM EDTA. The cells were removed from the dish with a rubber policeman and homogenised in a Dounce homogeniser. The homogenate was centrifuged at 104,000g for 1 h. The resulting cytosol was incubated at 0 °C with 3×10^{-8} M ^3H -DOC (48 Ci mmol, New England Nuclear). An aliquot was also incubated with 3×10^{-8} M ^3H -DOC + 3×10^{-5} M non-radioactive DOC. After 2.5 h at 0 °C, aliquots from the 3×10^{-8} M ^3H -DOC sample were incubated with 1 mM PMSF, 1 mM TLCK, 0.5 mM TPCK, or 3×10^{-5} M non-radioactive DOC for 1 h at 0 °C. Bound steroid was separated from unbound steroid on BioGel P-10 columns (1 × 10 cm). Samples were done in duplicate and the results averaged. Variation was less than 10%. Fractions were counted in a liquid scintillation cocktail containing Omnifluor (New England Nuclear), Triton X-100 and toluene. Thin-layer chromatography, 100 min using dichloromethane-acetone (80:20) as the developing solvent, shows that incubation of ^3H -DOC with PMSF, TPCK or D-TME does not alter the chromatographic behaviour of ^3H -DOC.

*220,300 c.p.m. per mg = 1.26×10^{-11} mol per mg protein.

Table 2 Dependence of inhibition of ^3H -DOC binding on the concentration of protease inhibitors

Compound	Concentration (M)	% Inhibition
TPCK	1.5×10^{-6}	97
	1.5×10^{-7}	88
	3.0×10^{-8}	38
PMSF	1.5×10^{-5}	50
	1.5×10^{-6}	34
TLCK	3×10^{-4}	47
	1.5×10^{-5}	28

MDCK cell cytosol (with 4 mM dithiothreitol in the homogenising buffer) was incubated with 3×10^{-8} M ^3H -DOC for 1.5 h. Aliquots were then incubated for 2.5 h with 6×10^{-6} M DOC, or the above compounds. Bound steroid was separated from unbound steroid on Sephadex G-25 columns. Per cent inhibition refers to the inhibition of specifically bound counts, determined by subtracting the amount of ^3H -DOC bound in presence of 6×10^{-6} M DOC from the amount of ^3H -DOC bound in the absence of 6×10^{-6} M DOC.

inhibitors interact directly with the DOC receptor. Since DOC binding was inhibited by concentrations of protease inhibitors that were several orders of magnitude greater than the concentration of ^3H -DOC (Table 1), we conducted more detailed studies at lower concentrations of inhibitor to determine if inhibition of DOC binding occurred at concentrations which would be indicative of stoichiometric reaction with the DOC receptor. We also sought to determine differences in the affinity of these compounds for the DOC receptor. As shown in Table 2, TPCK apparently has a high affinity for the DOC receptor, since only a fivefold excess concentration inhibits DOC binding by nearly 90%. Furthermore, PMSF, TPCK, and TLCK all have different affinities for the DOC receptor in MDCK cells.

Such inhibition of DOC binding by protease inhibitors could be due to interaction either with a specific structure in the DOC receptor that recognises protease inhibitors or of a nonspecific type that denatures the DOC receptor. One way in which TPCK or TLCK might denature the DOC receptor would be to bind the thiol groups⁶⁻⁸ on the receptor. This possibility is unlikely, however, since TLCK and TPCK can inhibit ^3H -DOC binding to MDCK cytosol in the presence of 4 mM dithiothreitol and since TPCK is effective at concentrations as low as 10^{-7} M.

Additional observations with protease substrates also support our postulate that the DOC receptor in MDCK cells contains a specific structure that recognises the protease inhibitors. Moreover, this specific structure may be similar to that recognised by the protease inhibitors in proteases. Table 3 shows that four protease substrates, *p*-toluenesulphonyl-L-arginine methyl ester (TAME), L-tryptophan methyl ester (TME), acetyl-L-tyrosine methyl ester (ATEE), and benzoyl-L-arginine ethyl ester (BAEE) inhibit ^3H -DOC binding to MDCK cell cytosol. A more detailed examination of the relationship of the structure of the substrate and its effectiveness as an inhibitor of DOC

Table 3 Effect of protease substrates on ^3H -DOC binding

Substrate	% Inhibition
1 mM L-TAME	88
1 mM D-TAME	95
10 mM L-TME	73
10 mM D-TME	78
1 mM D-TME	25
1 mM L-ATEE	43
5 mM L-BAEE	60

Inhibition of binding of 3×10^{-8} M ^3H -DOC to MDCK cytosol by protease substrates was measured as described in Table 1, except that 4 mM dithiothreitol was included in the homogenising buffer.

binding was conducted for arginine and derivatives (Table 4). D-TAME produced 76% inhibition at 1.5×10^{-6} M, while 6×10^{-5} M tosyl-L-arginine was required to produce 46% inhibition and 10^{-2} M L-arginine produced only 17% inhibition. These findings emphasise the importance of the ester structure in effecting inhibition of DOC binding.

We then determined if protease substrates and inhibitors reversibly inhibit ^3H -DOC binding to its receptor. MDCK cytosol was incubated with 3×10^{-8} M ^3H -DOC and D-TME to eliminate specific ^3H -DOC binding. The inhibited cytosol was filtered through a Sephadex G-25 column to remove unbound D-TME, and the filtrate could then bind ^3H -DOC (Table 5). Similar results were found for inhibition of ^3H -DOC binding to MDCK cell cytosol by D-TAME. We conclude that the inhibition of ^3H -DOC binding to MDCK cytosol by D-TME and D-TAME is reversible. In contrast, a similar experiment with the protease inhibitor TPCK showed that the inhibition of DOC binding by TPCK is not reversible (Table 5). This suggests that TPCK binds covalently to the DOC receptor, as would be expected since TPCK is a covalent inhibitor of chymotrypsin.

Table 4 Dependence of inhibition of ^3H -DOC binding on the concentration of protease substrates

Compound	Concentration in cytosol (M)	% Inhibition
L-TAME	1.5×10^{-5}	55
D-TAME	6×10^{-6}	95
	1.5×10^{-6}	76
Tosyl-L-arginine	1.5×10^{-4}	84
	6×10^{-5}	46
L-Arginine	1.0×10^{-2}	17
	5×10^{-3}	3

MDCK cell cytosol (with 4 mM dithiothreitol in the homogenising buffer) was incubated with 3×10^{-8} M ^3H -DOC for 1.5 h. Aliquots were then incubated for 2.5 h with 6×10^{-6} M DOC, or the above compounds. Bound steroid was separated from unbound steroid on Sephadex G-25 columns. Per cent inhibition refers to the inhibition of specifically bound counts, determined by subtracting the amount of ^3H -DOC bound in presence of 6×10^{-6} M DOC from the amount of ^3H -DOC bound in the absence of 6×10^{-6} M DOC.

Although the details of the mechanism of inhibition of ^3H -DOC binding are not known, several structural features might be anticipated from the well understood mechanism of inhibition of proteases by PMSF, TLCK and TPCK^{2-6,9}. PMSF inhibits a broad class of proteases by binding covalently to the active serine residue, while TLCK and TPCK inhibit by binding covalently to a histidine residue spatially adjacent to the serine. Since both protease substrates and inhibitors prevent DOC binding, it is possible that a structure similar to that of the serine proteases is present in the DOC receptor. The DOC receptor is unique, however, in binding both a trypsin substrate (TAME) and a chymotrypsin inhibitor (TPCK). This might be expected for a receptor that recognises a steroid nucleus rather than specific amino acid residues.

An important question is whether protease inhibitors and substrate recognise only the DOC receptor or a structural feature common to several steroid binding proteins. Our evidence suggests that the inhibition of steroid binding by protease inhibitors and substrates is a more general phenomenon. For example, PMSF, TLCK, TPCK, TME, and TAME inhibit the binding of ^3H -oestradiol to purified rat α foetoprotein (M.B. and D.F., in preparation). In addition, PMSF, TLCK, and TPCK inhibit the binding of ^3H -dexamethasone and ^3H -oestradiol

to rat kidney cytosol (M.E.B., N. Anderson, D. Vaughn, and D.F., unpublished results).

From our results, we cannot indicate whether the steroids and protease inhibitors and substrates bind to the same active site in the steroid receptor or if there is a specific catalytic function associated with the ability of steroid receptors to bind protease inhibitors and substrates.

Table 5 Reversibility of inhibition of DOC binding

Condition	% Inhibition by TME (15 mM) TPCK (1.5 μM)	
a, Inhibitors present with ^3H -DOC-receptor complex for 1 h*	92	100
b, Inhibitors in (a) removed by filtration on G-25 Sephadex; followed by re-equilibration with ^3H -DOC for 2 h†	9	95

*MDCK cell cytosol was incubated with 3×10^{-8} M ^3H -DOC for 2 h then aliquots were incubated for 1 h with 15 mM D-TME or 1.5×10^{-6} M TPCK. Bound steroid was separated from unbound steroid on Sephadex G-25 columns.

†Aliquots of 1 ml cytosol which had been incubated with 3×10^{-8} M ^3H -DOC for 3 h with or without 15 mM D-TME or 1.5×10^{-6} M TPCK for 1 h in (a) were filtered on Sephadex G-25 columns to remove unbound ^3H -DOC, D-TME, or TPCK. Then the filtrate was incubated with 3×10^{-8} M ^3H -DOC with or without 6×10^{-6} M DOC for 2 h. Bound steroid was separated from unbound steroid on Sephadex G-25 columns. % Inhibition refers to the inhibition of specifically bound counts, which were determined by subtracting the amount of ^3H -DOC bound in the presence of 6×10^{-6} M DOC from the amount of ^3H -DOC bound in the absence of 6×10^{-6} M DOC.

Nevertheless, two important applications of our results should be noted. First, the reversible inhibition of steroid binding by the D forms of TAME and TME suggest that it may be possible to purify steroid receptors by using the protease substrates as the ligand in affinity chromatography. To date, most attempts at purification of steroid receptors by affinity chromatography using steroid ligands have been unsuccessful, apparently because the high affinity of the steroid ligand for the receptor makes difficult the elution of the receptor in an active state or in high yield^{10,11}. With D-TAME or D-TME, however, the lower affinity of the steroid receptor for the protease substrate could improve the yield of receptor. Second, a new class of compounds which could react with steroid receptors *in vivo* is suggested. PMSF, TPCK, and TLCK enter cells, covalently, interact with proteins, and are unstable at pH 7.4 (37 °C)¹². Therefore, inhibitors could react with steroid receptors regionally with little toxicity or effect in areas of the organism distant from the point of application. Such compounds, or more selective protease inhibitors, might prove useful in treating localised steroid dependent tumours. The ability of protease inhibitors and substrates to block steroid binding to receptors may thus provide information on both structure and function of the steroid receptors.

We thank D. Vaughn for assistance and Dr N. Anderson for discussion of his model of formation of steroid receptors from proreceptors in cell cytosol. This work was supported by grants from the USNIH (USPHS AM 14915 and USPHS CA 15796).

Non-sequential expression of multiple immunoglobulin classes by isolated B-cell clones

As humoral immunity to a given antigen is generally thought to display an early IgM response which is later dominated by IgG synthesis, it has long been thought that clones of antibody-producing cells switched from μ to γ (refs 1-5). The sequence of appearance of immunoglobulin classes produced by the progeny of isolated precursors (B cells) to antibody-forming cells may answer the questions (1) does a clone of cells switch from μ to γ to α , and (2) do all clones switch in the same order following antigen stimulation? Results presented here show that there is no order of expression of immunoglobulin class with time by B-cell clones stimulated by antigen in the presence of carrier help, because any class can appear first or simultaneously with any other class.

Antibody polypeptides are encoded by separate variable (V) and constant (C) genes which are subsequently joined at the DNA level during lymphocyte differentiation to code for one polypeptide chain. Considerable chemical, genetic, and serological evidence has accumulated supporting the 'two gene-one polypeptide' theory proposed by Dreyer and Bennett in 1965⁶. Different V regions, as defined by subgroup-specific amino acid sequences, allotypic or idiotypic determinants, are found in association with a single C region for each of the κ and λ light (L) chain and heavy (H) chain loci⁷⁻⁹. Conversely, one V_H region can be shared by several different C_H regions¹⁰⁻¹⁵. In view of the finding by Hozumi and Tonegawa¹⁶ that V and C genes coding for L chains are on separate restriction fragments in embryonic DNA but are on the same restriction fragment in myeloma DNA, it is apparent that gene translocation may have a central role in immunoglobulin synthesis and cell differentiation¹⁷.

As there are multiple C_H genes that can be associated with a single V_H gene, the question arises as to whether the C_H genes are expressed in a sequential order following antigen stimulation. Several studies suggest that one cell or its clonal progeny can produce more than one immunoglobulin class. B cells have been shown to bear membrane receptor molecules of the IgM and IgD class with the same idiotype¹⁸. Using the splenic focus assay, we have previously demonstrated that a single antigen-stimulated B cell can produce clonal progeny making antibodies with different H chain classes that seem to have the same variable region by idiotypic analysis¹⁹. Thus, an isolated B-cell precursor specific for the phosphorylcholine (PC) determinant can be stimulated *in vitro* to generate daughter plasma cells which secrete antibody of three immunoglobulin classes, μ , γ 1, and α . Also, antibody molecules of each class have the same idiotype as that of the TEPC 15 (T15) myeloma. As shown here, an analysis of the sequence of appearance of constant regions within such T15 clones suggests that classes of immunoglobulin are produced in a random fashion following antigen stimulation in the presence of carrier help.

Ten million spleen cells from non-immune BALB/c mice were transferred intravenously into lethally irradiated BALB/c recipients that had been primed with 0.1 mg of *Limulus polyphemus* haemocyanin 2 months previously. Sixteen hours after transfer, spleen fragment cultures were prepared from the recipients and stimulated *in vitro* with 5×10^{-7} M 3-(azophenylphosphorylcholine)-N-acetyltyrosylglycylglycine haemo-

cyanin²⁰. The antigen was removed by day 4, and culture fluids were collected every 2 d until day 18. Anti-PC antibody was quantified by radioimmunoassay for heavy chain class and idiotype using T15 protein and monoclonal culture fluids as standards. The binding of antibody to antigen coupled to bromoacetylcellulose immunoadsorbant was detected with ¹²⁵I-labelled goat anti-mouse μ , γ 1, and α -chain antibody. Antibody with the T15 idiotype was detected in a radioimmunoassay using anti-T15 sera raised in A/He mice²¹. The monoclonal nature of antibody from these cultures has been demonstrated in previous experiments, indicating that each clone is derived from a single B cell^{19,22}.

The serial analysis of immunoglobulin class production by clones with the T15 idiotype indicates variation in time of appearance after stimulation, amount of antibody, and sequence related to other classes. The overall view of the onset of antibody production, shown in Fig. 1, suggests that any one of the three classes of immunoglobulin may be synthesised initially, and that IgG1 secretion persists longer than secretion of the other two classes. The apparently random expression of each immunoglobulin class is confirmed by data collected from individual clones which are presented in Table 1. B-cell clones, although making antibody with the same idiotype, display considerable variation in the rate of IgM, IgG1, and IgA production with time. Immunoglobulin class expression seems to be completely random in that any class of immunoglobulin can appear at any time, either singly or in combination with others. Variations in time of synthesis after stimulation and in amount of antibody in each immunoglobulin class produced by individual clones are observed. In an analysis of over 60 clones making antibody with the T15 idiotype, the early production of solely IgM and later solely IgG1 (or IgA) was not observed. Indeed, some clones made IgG1 before or without detectable IgM synthesis.

Fig. 1 Heavy chain class secretion by PC-specific clones with the T15 idiotype. The average amount of antibody produced by 43 clones in each immunoglobulin class is plotted as a function of time. Monoclonal fragment cultures were stimulated with antigen on day 1 and the antigen was removed on day 4. Culture fluids were collected every two days after that and analysed for idiotype and C_H determinants by radioimmunoassay.

The idea of an IgM to IgG 'switch' arose from observations that IgM is detected before IgG antibody in immune sera^{1,2}. Several explanations may be offered for these results. First, the assays used for IgM detection are more sensitive than those used for IgG detection. Second, it may be necessary to generate carrier-specific help to allow maximum expression of classes of immunoglobulin other than IgM; that is, IgM may appear first during the immune response because it requires less carrier-specific help. Thus, in physiological conditions, T cells or factors may influence the expression of heavy chain classes. Finally, subsets of B cells may have different developmental potentials for expressing C_H regions. For example, the clonal progeny of immature B cells produce predominantly IgM, whereas clones derived from immune B cells produce predominantly IgG²². Nonetheless, using a method which detects each heavy chain class equally well and provides

Table 1 Random production of immunoglobulin class by B-cell clones with time after antigen stimulation

maximal carrier help for the stimulation of nonimmune B cells, the data presented here clearly indicate that the onset of expression of different immunoglobulin classes is completely random in that any class can appear singly or in combination with others. In this regard, no evidence was found for a sequential shift from $\mu \rightarrow \gamma 1 \rightarrow \alpha$ by stimulated clones.

There are two general models for the association of V_H genes with their corresponding C_H genes¹⁵. The simultaneous insertional model suggests that the V_H gene is copied multiple times and is associated with two or more C_H genes. The successive insertional model proposes that the V_H gene is successively translocated to various C_H genes during differentiation. The data presented here suggest that if the first model is correct, random expression of a V_H - C_H gene combination occurs, whereas if the second model is correct, a V_H gene can be translocated next to any C_H gene following antigen-triggered differentiation. These two models can probably only be tested by direct studies at the nucleic acid level.

Immunoprotection by embryonal carcinoma cells for methyl-cholanthrene-induced murine sarcomas

METHYLCHOLANTHRENE-induced sarcomas of mice (MCS) usually have transplantation antigens specific to each independently arising tumour¹. These antigens, defined by *in vivo* protection assays, are different from those defined serologically as viral² or embryonic antigens^{3,4}. The latter, common to most sarcomas, seem to contribute little in transplantation assays as cross protection is rare and weak^{1,5}. The occasional success in protecting against sarcoma growth by previous immunisation with cells of mid-term embryos^{4,6} encourages the search for more effective ways of using common embryonic antigens for this purpose. We

show here that effective immunisation against several different non-cross-reacting sarcomas, including one not immunogenic itself, can be achieved with embryonal carcinoma cells. These cells are the stem cells of a teratocarcinoma and show remarkable similarities to the pluripotent cells of early mouse embryos with regard to cell surface antigens⁷ as well as in morphological and biochemical properties⁸.

The sarcomas used were a set induced in female C57BL/10ScSn (B10) mice by subcutaneous injection of 0.5 mg 3-methylcholanthrene into the hind legs. Approximately 100 d later primary tumours were excised, passaged subcutaneously twice and then stored in liquid nitrogen. Tumours (*in vivo* passages 2–8) were characterised for immunogenicity in a rejection assay (Fig. 1). To assay immunogenicity, mice were immunised in two ways: by allowing tumour growth for 10 d followed by tumour excision or by three weekly immunisations with 10^7 irradiated MCS cells (legend Fig. 1). The mice were challenged a week later with 2×10^5 viable cells of the same or a different sarcoma and tumour diameter measured as a function of time.

Fig. 1 Immunogenicity of methylcholanthrene-induced sarcomas MC6A and MC6B. Groups of 12 female B10 mice, 12–16 weeks old were immunised by three weekly subcutaneous injections of 10^7 MC6A or MC6B cells (irradiated with 10,000 rad from a ^{60}Co source) in 0.2 ml phosphate-buffered saline (PBS) into the right groin. Tumour cell suspensions were prepared from *in vivo* tumours chopped finely and stirred continuously at 37 °C in 2.5% trypsin in Eagles Ca^{2+} - and Mg^{2+} -free medium. One week following the last immunisation, groups of six mice were challenged with 2×10^5 viable MC6A (a) or MC6B (b) cells in 0.2 ml PBS into the right groin. Control groups of unimmunised mice were similarly challenged. Tumour diameter was measured in two perpendicular planes every 3 d using calipers for 16 d after challenge. Error bars represent \pm s.e.m. \circ , unimmunised; Δ , MC6A immunised; \square , MC6B immunised.

Figure 1 shows that MC6A and MC6B are strongly immunogenic; immunisation evokes good protection against subsequent challenge with the same methylcholanthrene sarcoma. A measure of the strength of immunisation is the antigenic ratio (AR) (ref. 9) (Table 1). The relative immunogenicity measured by AR ranks the tumours in the descending order MC6A, MC6B, MC9, MC5 with MC5 being non-immunogenic (Table 1). Data in Fig. 1 and Table 1 also demonstrate that MC6A and MC6B do not cross protect and thus apparently possess individually specific antigens.

Similar immunisations with cells of an embryonal carcinoma cell line Nulli-SCC.1, which do not differentiate *in vivo* or *in vitro*¹⁰, elicit protection against the strongly immunogenic MC6A and MC6B, the less immunogenic MC9, and the non-immunogenic MC5 (Table 1, Fig. 2a, b and c). The Nulli-SCC.1 cells are derived from the 129/J mouse strain which is not syngeneic with B10. To test whether alloantigens on Nulli were responsible for the protective effect against the sarcomas, 129/J spleen cells were used to immunise B10 mice; no protection was seen (Fig. 2d). In addition, immunisation with cells of C57BL/6 thymoma EL4 (ref. 11), a DBA/2 mastocytoma P815 (ref. 12), or a B10A Abelson lymphoma induced in our laboratory, gave no protection against subsequent challenge with MC6A cells (Fig. 2d). The Nulli-SCC.1 cells grow as homogeneous embryonal carcinoma *in vitro* and the cell line was derived from a spontaneous testicular teratocarcinoma (LS-402C-1684). These Nulli-SCC.1 cells resemble

Table 1 Relative immunogenicity of methylcholanthrene sarcomas and embryonal carcinoma with MCS challenge

Immunising tumour*	Challenge tumour†	Antigenic ratio‡
MC6A	MC6A	10.0
MC6B	MC6A	1.1
MC6A	MC6B	1.0
MC6B	MC6B	5.3
MC9	MC9	3.2
MC5	MC5	1.0
Nulli-SCC.1	MC6A	2.1
Nulli-SCC.1	MC6B	2.0
Nulli-SCC.1	MC9	1.9
Nulli-SCC.1	MC5	1.7

* 10^6 viable tumour cells prepared as in Fig. 1 were injected in 0.2 ml phosphate buffered saline (PBS) into the left flank of groups of four mice and tumours excised surgically 10–14 d later. Nulli-SCC.1 cells were grown as monolayers in tissue culture and cell suspensions prepared as previously described⁸.

† 2×10^5 viable cells were injected subcutaneously (s.c.) in 0.2 ml PBS into the right groin 10 d after the excision. Tumour diameter was measured in two perpendicular planes every 3 d by calipers and the mean calculated. A control group of unimmunised animals was challenged concurrently.

‡Antigenic ratio is calculated as

$$\frac{\text{mean tumour diameter in unimmunised mice}}{\text{mean tumour diameter in immunised mice}}$$

at 16 d after challenge. An antigenic ratio of greater than 1.0 indicates protection. Mean tumour diameter is computed from all mice in a group; no challenge dose failed to grow in these experiments.

early embryo cells in morphological, biochemical and antigenic properties¹³, but differ because they can no longer differentiate. Immunisation with irradiated homogeneous embryonal carcinoma cells from a pluripotent teratocarcinoma cell line¹⁰ also shows protection against challenge with MC6A tumour cells. This line was isolated from a 3-d embryo induced teratocarcinoma (OTT-5568) and retains the ability to differentiate *in vivo* and, in appropriate conditions, *in vitro*.

In addition to embryonal carcinoma, some protection against methylcholanthrene tumour challenge is also provided by immunisation with teratocarcinoma derived endodermal cells of the lines PSA5E (ref. 13) and PYS-2 (ref. 14) (Fig. 2e), though the

Fig. 2 Protection by various cells against MCS challenge. Groups of 3 B10 female mice were immunised by three weekly s.c. injections of 10^7 cells. A week following the last immunisation, the mice were challenged with 2×10^5 viable tumour cells as in Fig. 1. a, b, and c. Mice immunised with irradiated Nulli-SCC.1 (Δ); unimmunised (\circ). Challenge with MC6A, MC6B, MC5 respectively. d. Mice immunised with irradiated EL4 (Δ); B10.A.A2.P5 Abelson lymphoma (\bullet); P815 mastocytoma (\blacktriangle); and 129 spleen cells (\square); unimmunised (\circ). Challenge with MC6A. e. Mice immunised with PYS (\bullet), PSA5E endodermal cells (Δ); unimmunised (\circ). Challenge with MC6A.

degree of protection by PYS is weak. These lines were derived from the outgrowths of embryoid bodies *in vitro*.

How do embryonal carcinoma cells induce protection to tumours that do not protect against each other (MC6A and MC6B) and to a tumour that cannot protect against itself (MC5)? Nonspecific activation of the immune system by the embryonic cell lines, though not by the other tumour lines tested, might explain the observed cross protection¹⁵. A more interesting possibility is that there are antigens shared by all these cells and that presentation of these antigens on the embryonal carcinoma cells is particularly effective in inducing specific immune protection while presentation of these common antigens on the MCS is not effectively immunogenic. Indeed serological studies with teratocarcinoma have demonstrated antigen specificities present on these cells and which are shared by a wide range of tumour cell lines^{16,17}. Antisera prepared by us in syngeneic mice against MCS cross react with embryonal carcinoma cells. In addition, lymphocytes sensitised *in vitro* to syngeneic teratocarcinoma cells have been shown to inhibit growth of a wide range of tumour cells *in vitro* and *in vivo*, but do not affect untransformed cells¹⁸.

Why the MCS-embryonal carcinoma shared antigens might be immunogenic only on the latter cells is intriguing. It is perhaps relevant that both the embryonal carcinoma and the endodermal cells do not express the major histocompatibility antigens (H2) (refs 13, 19). Since there is increasing evidence that H2 plays an important part in directing the immune response²⁰, it is possible that in the absence of H2 expression, other antigens, not seen in the presence of H2, become immunodominant.

Chemical mutagenesis of mammalian cells can be quantified

STUDY of mammalian genetics has been traditionally limited to conventional breeding experiments, which are limited by high cost, long duration and the availability of well-characterised genetic markers. These factors have especially impeded rapid progress in mammalian mutagenesis studies. Many of the mechanisms underlying the process of mutation induction in mammals can be investigated through the use of mammalian cells in culture¹⁻³, but the use of cultured cells for quantitative analyses of mutagenesis has been hampered by the lack of a suitable mutation-induction system, particularly with chemical mutagens. We show here that quantitative dosimetry of chemical mutagenesis can be studied in a mammalian cell culture system. This will allow

Fig. 1 Expression time of HGPRT⁻ (TG-resistant) mutant phenotype. CHO cells (clone K₁-BH₄) were plated at 5×10^5 cells per 100-mm plate in Ham's F12 medium containing 5% dialysed foetal calf serum and were incubated at 37 °C in 5% CO₂ in air in a 100% humidified incubator. After 24 h (cell no. $1-1.5 \times 10^6$ cells per plate), EMS was added (zero time), and the cultures were incubated for 16 h. The cultures were washed three times with saline, the cells were removed by trypsinisation, and approximately 10^6 cells were subcultured. For selection of the mutant phenotype, cells were plated at 2×10^5 cells per 100-mm plate (5 plates = 10^6 cells) in hypoxanthine-free F12 medium containing 5% dialysed foetal calf serum and 10 µM TG. For cloning efficiency, 200-1,000 cells were plated in triplicate in the same medium without TG. After 7 d of growth colonies were fixed, stained, and counted. Cultures were also subcultured and plated for mutant selection every 2 d thereafter. Mutation frequency was calculated as the number of mutant colonies per 10^6 cells (corrected by cloning efficiency at time of selection). Cells treated with 0 (Δ), 50 (▲), 100 (□), 200 (■), or 400 (○) µg ml⁻¹ of EMS. Spontaneous frequency in the range $2-3.6 \times 10^{-6}$.

not only studies of the mechanisms of chemical mutagenesis, but also an estimate of the genetic hazard of chemical agents in the environment.

The mutation assay system we have developed uses cultured Chinese hamster ovary (CHO) cells and the purine analogue 6-thioguanine (TG) to quantitate mutation induction at the hypoxanthine-guanine phosphoribosyl transferase (HGPRT) locus⁶. This CHO/HGPRT system is based on the facts that TG is converted to the nucleotide by the HGPRT activity of wild-type cells and that the nucleotide or its metabolites are lethal. Mutant cells lacking this enzyme activity are able to survive and grow in the presence of TG. We have defined optimal conditions for the selection of the mutant phenotype, including phenotypic expression time, concentration of TG and medium composition for the selection step, and optimal cell density in the selection to permit maximum mutant recovery. With our system the TG-resistant mutation seems to affect the HGPRT locus almost exclusively, since more than 98% of the resistant clones show greatly reduced incorporation of radiolabelled hypoxanthine into macromolecules, are sensitive to the anti-metabolite aminopterin, and contain highly reduced or undetectable HGPRT activity (ref. 6 and O'Neill, J. P., Brimer, P. A., Machanoff, R., Hirsch, G. P., and Hsie, A. W., submitted for publication). Using the CHO/HGPRT system, we have studied mutagenesis with a common chemical mutagen, ethyl methanesulphonate (EMS), in a quantitative fashion.

An important aspect to consider in any mutation induction is phenotypic delay, the time required for mutants to express the altered phenotype. For TG resistance, a delay would be expected due to the time necessary for the dilution and decay of pre-existing HGPRT enzyme and its mRNA before the mutant phenotype could be expressed. This important parameter was investigated with cultures incubated with various concentrations of EMS for 16 h;

Fig. 2 Dose response of EMS-induced mutagenesis. Data from two separate experiments are presented: the average of the mutation frequencies at days 7, 9, 11, and 13 from Fig. 1 (Δ) (average spontaneous frequency 3.1×10^{-6}); and the frequencies for 24-h incubation time from Fig. 3 (□).

thereafter, the cells were subcultured and plated for selection every 2 d. Mutant colonies were found after 5 d of expression, and the mutation frequency reached a maximum value at day 7 with all EMS doses (Fig. 1). The expression time was independent of the mutagen dose, and there was no loss of mutants with longer periods of expression, as the mutation frequency remained at a constant value in cells subcultured for an additional 6 d. There was a linear dose-response relationship between mutation frequency and EMS concentration (Fig. 2). Since the mutation frequency reached a stable maximum value at 7–9 d of expression, cells were routinely plated for selection on day 9 in all subsequent experiments.

The dose-response data of Fig. 2 were obtained with long incubation times with EMS (16–24 h). It would be difficult to compare such chemical mutagenesis with that induced by physical agents like X rays because of complicating factors such as the stability of EMS in the medium, rate of cellular uptake, and intracellular stability. To investigate these aspects, cultures were incubated with EMS for

Fig. 3 Initial cell survival (a) and EMS-induced mutation frequency (b) as a function of incubation time. Cells were plated at 5×10^5 cells per plate as described in Fig. 2. After 24 h, EMS was added, cultures were incubated for the indicated time interval and then washed, and fresh medium was added. After a total interval of 24 h the cultures were trypsinised, and single-cell survival was determined (absolute cloning efficiency of untreated control cultures was 84%). Cultures were subcultured every 2 d and plated for mutant selection on day 9 of expression as described in Fig. 1. EMS at concentrations of 50 (Δ), 100 (▲), 200 (□), and 400 $\mu\text{g ml}^{-1}$ (■). Spontaneous mutation frequency 4.2×10^{-6} .

intervals of 2–24 h. A linear increase in mutation frequency with incubation times of up to 12–14 h was found with EMS concentrations of 50–400 $\mu\text{g ml}^{-1}$ (Fig. 3b). But cell survival decreased exponentially with time over the entire 24-h period (Fig. 3a). This difference in the time courses of cellular lethality and mutagenicity might be due to the formation of toxic, non-mutagenic breakdown products in the medium with longer incubation times or might reflect a difference in the mode of action of EMS in these two biological effects. The increases in both cell lethality and induced mutation with incubation times of up to 12 h allow a study of the dosimetry of this chemical mutagen. For better defined dosimetry studies, cultures were incubated with various concentrations of EMS (0.05–3.2 mg ml^{-1}) for 2–12 h. As shown in Fig. 4 the decrease in cell survival was exponential with dose ($\text{mg ml}^{-1} \text{ h}$), and the increase in mutation frequency was linear with dose. From these studies the mutagenic potential of EMS can be described as 310×10^{-6} mutants ($\text{cell mg ml}^{-1} \text{ h}$) $^{-1}$.

Fig. 4 Dosimetry for EMS cellular lethality (a) and induced mutation frequency (b). Cells were treated with various concentrations (mg ml^{-1}) of EMS for 2 (Δ), 4 (▲), 8 (□), or 12 h (■). After treatment the cultures were washed, and single-cell survival was determined after a total time of 24 h. Cells were plated for selection on day 9 of expression as in Fig. 2. Spontaneous mutation frequency = 2.3×10^{-6} . In (a) the linear fit of the survival curve was found over 1.6–6.4 $\text{mg (of EMS) ml}^{-1} \text{ h}$ through fitting to the 'multitarget model'

$$R_i = 1 - (1 - e^{-Bx})^N$$

where B and N are fitted coefficients. The extrapolation number (N) is 1.74 with 95% confidence limits of 1.18, 2.58; the slope (B) is -0.248 with 95% confidence limits of -0.308 , -0.188 . In (b) the straight-line fit for the pooled data on mutation induction over the dose range 0.64–6.4 $\text{mg (of EMS) ml}^{-1} \text{ h}$ is $f(x) = 10^{-6} (5.58 + 310.77x)$. The 95% confidence limits for the slope are 283.68, 337.87. All confidence limits are estimated based on the residual sum of squares. Statistical analyses were performed as in ref. 6.

These results demonstrate (1) that the mutagenicity of EMS in mammalian cells follows a linear dosimetry relationship, and (2) that a quantitative study of chemical mutagenesis in mammalian cells is possible if an adequately defined selection protocol is developed.

We thank M. H. Hsie, D. G. Gosslee and T. J. Mitchell for help with statistical analysis and D. B. Couch and E. I. Shaw for reviewing the manuscript. This work was supported by the US National Center for Toxicological Research, EPA and ERDA under contract with the Union Carbide Corporation.

Increasing ovulation rate in sheep by active immunisation against an ovarian steroid androstenedione

ALTHOUGH low rates of ovulation constitute a major limitation to increased productivity of sheep and cattle little is known about the mechanisms that control ovulation either within or among species. Androstenedione, a weak androgen secreted by ovaries¹ and adrenals¹, is quantitatively the major steroid secreted by the ovary before ovulation in several species² and as such it might have a role in determining ovulation rate; it is also an important precursor for the biosynthesis of oestrogens by the ovary³. Although androstenedione can act as a prehormone by virtue of its peripheral metabolism to oestrogens⁴, a direct hormonal action has only been demonstrated in the female rhesus monkeys⁵ where it seems to be important for sexual behaviour. We report here that by actively immunising sheep against androstenedione a slight but significant increase in ovulation rate can be induced.

Two series of experiments were carried out on 10 Welsh mountain ewes. Half of the sheep were immunised against androstenedione conjugated in the 11 position to bovine serum albumin (BSA)⁶ and the other half were immunised against BSA alone and served as controls. All of the ewes immunised against androstenedione-11-BSA produced antibodies with a high degree of specificity for androstenedione⁶, and the titre of antibody was maintained at elevated levels by periodic booster immunisations⁶.

During the normal sheep mating season (October-March) the ewes were kept with a harnessed vasectomised ram and observed daily for signs of oestrus⁷. In March 1975, and again in November 1975, the ewes were subjected to a laparotomy and the number of corpora lutea and visible Graafian follicles of greater than 4 mm diameter were recorded. The pooled results are presented in Table 1 and show that there was a significant increase in the ovulation rate (Fisher's exact test, $P < 0.01$, February 1975; $P < 0.07$, November 1975) but the length of the oestrous cycle and the duration of oestrus were unaffected (t test). The increase in ovulation rate was accompanied by an increase in follicular growth, the control ewes having 1.6 ± 0.2 Graafian follicles per animal in contrast to 4.2 ± 0.7 per ewe in the immunised group ($P < 0.05$, Wilcoxon rank sum test).

Table 1 Length of oestrous cycle, duration of oestrus and ovulation rate in sheep immunised against androstenedione-11-BSA

Group	Oestrous cycle (d) (mean \pm s.e.m.)	Duration of oestrus (h) (mean \pm s.e.m.)	Ovulation rate (mean \pm s.e.m.)
Control	16.7 ± 0.2 ($n = 56$)	40.4 ± 1.3 ($n = 10$)	1.11 ± 0.11 ($n = 9$)
Immunised	17.5 ± 0.8 ($n = 70$)	45.1 ± 1.9 ($n = 7$)	2.13 ± 0.12 ($n = 8$)

These experiments clearly show that ovulation rate can be increased by immunisation against androstenedione-11-BSA. This technique has the additional advantage that excessive superovulation such as is often produced by the use of exogenous gonadotrophins is avoided: all of the immunised ewes had either two or three ovulations, while all the control ewes had one or two ovulations. In subsequent experiments on larger groups of sheep only 1 out of 15 immunised ewes had an ovulation rate of greater than 3.

Measurement of the peripheral levels of luteinising hormone

(LH) (ref. 8) and progesterone⁶ in samples collected daily throughout one complete oestrous cycle are shown in Fig. 1. The ewes immunised against androstenedione-11-BSA had elevated peripheral concentrations of both hormones throughout most of the oestrous cycle. An additional series of blood samples was collected from both groups of ewes, the collections beginning at 0800 LT on day 16 of the oestrous cycle and continuing at 4-h intervals until 36 h after the onset of oestrus. The plasma samples were assayed for the LH content, and the results show that the preovulatory LH discharge reached its maximum concentration 24 ± 4.0 h (mean \pm s.e.m. $n = 3$) after the onset of oestrus in the immunised ewes as compared with 8 ± 1.3 h ($n = 5$) in the control group ($P < 0.001$; unpaired t test).

These experiments suggest that androstenedione has a role (possibly direct) in the control of ovulation rate and, furthermore, that androstenedione might provide a manifestation of the genetic expression of ovulation rate. The mechanisms involved in

Fig 1 The mean \pm s.e.m. peripheral concentrations of progesterone (lower) and LH (upper) throughout the oestrous cycle of ewes immunised against androstenedione-11-BSA (\bullet , $n = 5$) and control ewes immunised against BSA (\circ , $n = 5$). The oestrous cycle is dated 8 d forward and 8 d back from successive oestrous periods. Note the split vertical scale for LH.

producing the increased ovulation rate and peripheral concentrations of progesterone and LH are speculative. Neutralisation of the biological activity of androstenedione by antibody binding could interfere with oestrogen synthesis in the ovary, or with the conversion of androstenedione to oestrogen in peripheral tissues and hypothalamus. Alternatively, androstenedione itself may have a direct inhibitory action on the hypothalamo-hypophyseal system. It is even possible that the androstenedione antibody cross reacts to a minor degree with oestrogens, although this cross reaction was shown to be less than 0.1% in an *in vitro* test⁸. Whatever the explanation, our results show that the ovarian steroid hormone(s) involved in the feedback control of LH have a reduced effectiveness after immunisation against androstenedione-11-BSA, and that this exposes the animal to higher tonic secretions of gonadotrophin which in turn leads to increased follicular development, multiple ovulations and enhanced progesterone secretion. A similar mechanism is thought

to operate when synthetic anti-oestrogens such as clomiphene are used to induce ovulation in anovulatory women⁹. The ability to produce a modest increase in the ovulation rate in sheep following a simple immunisation procedure could be of practical significance, provided that the increased ovulation rate leads to an increased number of live births per sheep mated.

We thank Dr G. Woods (Organon Laboratories, Newhouse, Scotland) and Dr F. Rutherford MRC Radioimmunoassay Team, Edinburgh) for preparing the androstenedione-11-BSA, and Mr J. B. Donnelly, CSIRO Division Mathematics and Statistics, for statistical advice. P. Van Look was supported by the National Fonds voor Wetenschappelijk Onderzoek, Brussels, Belgium.

Is α MSH a trophic hormone to adrenal function in the foetus?

FUNCTIONAL development of the pituitary-adrenal axis in the foetus seems to be of considerable importance in influencing the maturation of other foetal organ systems, and the timing of parturition^{1,2}. In several species including man^{3,4}, sheep⁵ and rabbits⁶, there is evidence for an increase in foetal adrenal function in late pregnancy, which seems to depend on the activities of the foetal pituitary and hypothalamus⁷. The factors responsible for stimulating foetal adrenal development during late gestation remain poorly understood, however. From detailed studies in foetal sheep, it is apparent that the prepartum acceleration of adrenal growth and glucocorticoid secretion is not preceded by elevated ACTH concentrations in the foetal plasma^{8,9}. But, prostaglandin E₂ (PGE₂) administered intra-arterially into the foetus stimulated an increase in the concentration of cortisol in foetal plasma⁸ at a stage of pregnancy when the adrenal gland was essentially unresponsive to endogenous or exogenous ACTH (refs 2, 9). Experiments in newborn lambs suggest that the pituitary or brain rather than the foetal adrenal gland was the likely site of the PGE₂ action¹⁰, raising the possibility that other pituitary peptides might mediate this effect. The ACTH related peptides, α -melanocyte stimulating hormone (α MSH) and corticotropin-like intermediate lobe peptide (CLIP) have been identified in human foetal pituitaries, and it has been suggested that the ratio of these peptides to ACTH might be critical to maturation of foetal adrenal function¹¹. We have examined the ability of one of these peptides, α MSH, to influence adrenal function in the rabbit foetus. We present here evidence that the foetal adrenal secretes cortisol in response to α MSH at stages in pregnancy when it is unresponsive to ACTH, but as the sensitivity to ACTH increases, the relative response to α MSH is diminished.

Pregnant New Zealand white rabbits were purchased from Canadian Hybrid Farms, Quebec on day 17 of gestation and were housed individually. The animals had been mated once with a fertile buck, and the day of mating was designated as day 0. Experiments were performed on foetuses on day 22 post coitum and day 28 post coitum and on newborn rabbits, 4-6 d-old after spontaneous delivery at full term.

Foetal experiments were performed under local (1% Xylocaine) anaesthesia. A laparotomy incision was made, the uterus exposed, and ACTH (10 μ g Synacthen, ACTH₁₋₂₄, CIBA), α MSH (10 μ g, Bachem) or saline was injected intramuscularly (i.m.) into the foetus through the uterine wall. All injections were made in 100 μ l saline. After injection, the uterus was replaced, and the abdomen closed with surgical clips. After 60 min the foetuses were delivered, decapitated, and the blood collected into chilled heparinised tubes and immediately frozen. Newborn rabbits, handled gently with gloves, were injected i.m. with ACTH, α MSH or saline as above, and returned to their mothers. After 60 min the newborns were removed and blood (0.5-1.0 ml) collected rapidly by cardiac puncture. All samples were frozen at -20 °C until analysis for cortisol using a previously described antibody⁴ and radioimmunoassay procedure^{8,12}.

An initial study in newborn rabbits examined the time course of the blood cortisol response to ACTH injection. The concentration of cortisol increased from 2.97 ng ml⁻¹ at the time of injection to a maximum concentration (10.9 ng ml⁻¹) within 60 min (Table 1). This time interval was therefore adopted in subsequent studies.

Table 1 Blood cortisol concentrations in foetal and newborn rabbits in response to exogenous α MSH or ACTH

Age	Control t_0	Cortisol (ng ml ⁻¹)		
		Saline t_{60}	Synacthen t_{60}	α MSH t_{60}
22 d p.c.	14.65 \pm 1.02	18.35 \pm 2.85	21.39 \pm 3.24	32.45 \pm 3.17**
28 d p.c.	6.60 \pm 0.82	6.13 \pm 1.57	7.94 \pm 0.83	10.54 \pm 0.80*
4-6 d p.p.	2.97 \pm 1.05	2.74 \pm 0.76	10.91 \pm 1.45***	6.93 \pm 1.36*

The values are the mean \pm s.e. of 10-18 foetuses or newborn from 2-13 mothers in each group. Control observations (t_0) were made before injections. Measurements were then made 60 mins (t_{60}) after saline, Synacthen, or α MSH. p.c., Post coitum; p.p., post partum. Significant differences from 'saline t_{60} ' are indicated as follows: *** P < 0.001, ** P < 0.005, * P < 0.05. Other mean values within any age group are not statistically significantly different from the corresponding saline t_{60} group.

There was no significant effect (P > 0.05) of saline injection on the blood cortisol concentration in any of the three groups of animals (Table 1). In foetuses 22 and 28 d post-coitum, Synacthen produced no significant change in the blood cortisol concentration, whereas a significant increase in cortisol (P < 0.001) was found 60 min after Synacthen injection in the newborn. In marked contrast, α MSH caused a significant increase in the concentration of cortisol in the blood of foetuses at 22 and 28 d post-coitum (Table 1). α MSH also increased the concentration of cortisol in the blood of newborn rabbits but the response relative to that achieved with Synacthen was less marked than earlier in gestation.

Although cortisol and corticosterone are present in similar concentrations in the blood of foetal rabbits⁵, cortisol binds more strongly than corticosterone to liver, kidney and lung receptor sites¹³, and in adults its secretion is stimulated preferentially by ACTH (ref. 14). We therefore measured cortisol as an index of foetal adrenal glucocorticoid production. The control (t_0) levels we have measured are similar to those reported by Mulay *et al.*⁵, who also observed a decrease in the plasma cortisol concentration between day 22 and 28. In view of the significant increase in body weight and blood volume of the rabbit

foetus between day 22 and 28, comparison of blood cortisol levels between these times are difficult to interpret, and a twofold concentration decrease may not necessarily reflect a decrease in total production rate. Total and unbound cortisol in plasma increase significantly by day 30 (ref. 5), providing evidence for a pre-partum increase in adrenal steroid secretion.

At days 22 and 28 post coitum there was no increase in cortisol in response to ACTH injection into the foetus. Albano *et al.*¹⁵, failed to stimulate adrenal cyclic AMP with ACTH at day 22, implying that the appropriate tropic hormone receptors are poorly developed at that time. A similar insensitivity of the foetal adrenal to ACTH has been reported in the sheep^{2,9} and rhesus monkey¹⁶. It is of interest that while ACTH did not produce short-term changes in the concentration of cortisol in foetal blood, it will maintain adrenal weights in hypophysectomised rabbit foetuses¹⁷, showing that any deficiency of ACTH receptor is not absolute. In contrast to the effects in the foetus, we have shown that in the newborn rabbit, as in the newborn primate¹⁸, ACTH will stimulate an increase in the blood concentration of cortisol.

In striking contrast to the ineffectiveness of ACTH, α MSH provoked a significant increase in the concentration of cortisol in the blood of rabbit foetuses at day 22. The response to α MSH, both absolute and proportional was less marked at day 28, although this could relate to the dose injected. In the newborn the response to α MSH relative to that with Synacthen was reduced further. Previous work has shown that adrenal cells from adult rabbits *in vitro* do not respond to hyperphysiological amounts of α MSH, although they do secrete cortisol in response to ACTH¹⁸. The possible role of hormones other than ACTH as trophic agents to the adrenal gland in the foetus has been suggested from studies in sheep^{8,9,10} and in man^{11,19}, where the ACTH-related peptides, α MSH and CLIP have been isolated from foetal pituitaries. Although the concentrations of these peptides relative to ACTH decreased during late gestation and after birth, it is apparent that they are the dominant peptides of foetal life^{8,11}.

While one cannot conclude from our study that α MSH is 'the' trophic hormone to foetal adrenal function in the rabbit, it is apparent that the foetal adrenal responds to it by day 22 of pregnancy, at a time it does not respond to ACTH. The observation that the foetus may respond to a trophic hormone which is ineffective in the adult is an interesting one, and suggests that it may be inappropriate to extrapolate from adult control mechanisms to those in the foetus. In that sense, it may be necessary to revise some of our concepts of underlying control mechanisms in foetal endocrinology.

We thank Drs F. Naftolin and D. K. Lee for helpful comments. The work was supported by the Fraser Memorial Trust of the Royal Victoria Hospital, the Quebec Research Council and the MRC of Canada. J.R.G.C. is a Canada MRC Scholar.

Local anaesthetic benzyl alcohol increases membrane thickness

WE present here evidence that the local anaesthetic, benzyl alcohol, causes a large expansion in the thickness (an increase of about 25% at 7.5 mM concentration) of the hydrocarbon region of bimolecular lipid membranes. Such a change in the bilayer fabric of nerve membranes would provide a new insight into the molecular basis of anaesthesia. While the primary process involved in the mode of action of the anaesthetic is apparently different from the possible effect on the boundary lipids around the sodium channel, recently suggested by Lee¹, the main features remain the same; the sodium channel becomes inoperative (closes?) due to a stress resulting from changes in the membrane's bilayer structure in the presence of the anaesthetic.

The effect of the benzyl alcohol on the thickness of the artificial lecithin bilayer membranes was studied using four-terminal measurements of the very low frequency (0.1–100 Hz) capacitance and conductance of artificial lecithin bilayers with the aid of a digital impedance measuring technique elsewhere^{2–4}.

The effect of benzyl alcohol on the hydrocarbon region capacitance is shown in Fig. 1a. At concentrations of over 7.5 mM, benzyl alcohol decreased the hydrocarbon region capacitance by more than 25%. The conductance of this region also increased in the presence of the anaesthetic (Fig. 1b).

In the absence of the anaesthetic, with a dielectric constant $\epsilon_H = 2.1$ for the hydrocarbon region², the bilayer has a hydrocarbon region thickness $\delta_H = 3.7$ nm. This is considerably less than twice the fully extended length of the hydrocarbon tails of the predominant lecithins in egg phosphatidylcholine. In the presence of the anaesthetic at 7.5 mM concentration the capacitance data yields a thickness^{2,4} of 4.9 nm for the hydrocarbon region. This is a little larger than twice the fully extended length of the hydrocarbon tails. In the absence of the anaesthetic the hydrocarbon tails therefore seem to be much folded, coiled, kinked (double-gauche forms may predominate) or even somewhat interdigitated.

The anaesthetic apparently has the effect of straightening out the hydrocarbon tails. This process is accompanied by an increase in the conductance of the membranes and, from independent nuclear magnetic resonance studies⁵, an increase in fluidity.

Although the presence of cholesterol in the membrane was found itself to decrease the hydrocarbon region thickness, we found that the effect of benzyl alcohol on lecithin-cholesterol membranes was similar to that reported here for pure lecithin bilayers when the electrolyte was 1 mM KCl.

Fig. 1 *a*, The effect of benzyl alcohol on the capacitance of the hydrocarbon layer of bimolecular lipid (lecithin) membranes. The membranes were formed in a 1 mM KCl solution to which the anaesthetic was added. *b*, The conductance of the hydrocarbon region for various concentrations of the anaesthetic. The general increase in the conductance of this region was associated with an increase also in the apparent, mechanical, fluidity of the membranes. The points shown are mean values from several sets of measurements on different membranes (average of 12 measurements per point). The vertical bars indicate the total experimental scatter.

The lecithin bilayer membranes were generated from films of lecithin in *n*-tetradecane and at high concentrations of benzyl alcohol it seems from the low values of the hydrocarbon region capacitance that significant quantities of the *n*-tetradecane may then have been retained in the membrane.

The change in the thickness on addition of the benzyl alcohol at 7.5 mM concentration amounts to ~ 1.2 nm. This is probably $> 15\%$ of the total length of the excitation conduction modules for sodium ions, which span the membrane. Such a strain could readily lead to a closure of the channel. This is shown schematically in Fig. 2. For illustration purposes the conduction channel is depicted with an outer ring of hydrophobic material which is somewhat thicker than the normal width of the hydrocarbon region

Fig. 2 Schematic representation of the proposed effect of benzyl alcohol on the structure of the bilayer membrane near a hypothetical sodium conduction channel embedded in it. For illustrative purposes, the latter is taken to have a hydrophobic portion (shown shaded) which is somewhat larger than the thickness of the hydrocarbon region of the unperturbed bilayer. The distortion of the bilayer to accommodate such a module together with the requirement of close packing of the fluid-like hydrocarbon portion necessitates the straightening of the fatty acid chains and a closer packing of the polar heads near the conduction module and leads to a radially outward tension on the module. When the hydrocarbon layer thickens in the presence of the anaesthetic, the bilayer is dimpled inwards around the module; this sets up a radial compressive stress on the module⁷. It is suggested that such changes in surface stress are associated with the loss of excitation by the membrane. Alternatively, the accompanying changes in the longitudinal stress in the conduction channel could also lead to inactivation of the gating mechanism.

of the bilayer. Israelachvili *et al.*^{6,7} and Israelachvili (personal communication) have shown from packing geometry and free energy considerations that this will of necessity lead to a distortion outwards of the bilayer system around the conduction module as indicated in Fig. 2*a*. As pointed out by Israelachvili, the extension of the hydrocarbon chains of the lipids adjacent to the protein module restricts their motion and hence reduces their configurational entropy which leads to surface stress as indicated by the arrows in the diagram.

We now propose that this stress would tend to strain the conduction module radially outwards, which would assist in keeping the sodium channel through this module open. When benzyl alcohol is present we have found that the bilayer hydrocarbon region thickness is increased by at least 25% (somewhat more if the benzyl alcohol increased the dielectric constant of this region). In nerve cells this would have the effect shown in Fig. 2*b*. The hydrocarbon region of the bilayer is now wider than the hydrophobic region of the conduction module, and the bilayer has become distorted inwards around the sodium channel. The surface forces now lead to a radial compression of the channel (see Fig. 2*b*) thus blocking conduction by the channel.

On the other hand, if the conduction module itself stretches to accommodate the changes in the hydrocarbon region of the bilayer, the resulting longitudinal strain could by itself lead to a radial closure, or otherwise interfere with the gating mechanism by way of a deleterious change in the conformation of the protein of the module. Alternatively cardinal sites on it would become buried (if only in the polar head region of the bilayer) as the hydrocarbon region expands. Both these possible effects could readily interfere with the function of many of the proposed excitation mechanisms (for example refs 8, 9).

We thank Dr J. N. Israelachvili of the Australian National University for a stimulating discussion of the packing of proteins in lipid bilayers and for a preprint of his publication on this subject. After submission of this paper we learnt of a manuscript submitted by D. A. Haydon *et al.* in which, on the basis of the effects of alkanes, they postulated a mechanism similar to that we propose here for the molecular basis of anaesthesia.

Quantum amplitude distributions point to functional unity of the synaptic 'active zone'

THE exact nature of the quantum is still not known. Several observations^{1–6} support the idea that transmitter is released from synaptic vesicles. Analyses based on the quantum hypothesis using Poisson^{7,8} or binomial statistics^{9,10} cannot

provide direct evidence for or against this idea, since quanta might equally well be produced by the opening and closing of membrane shutters allowing release of cytoplasmic transmitter. All these considerations rest on the assumption that a single quantum is due to the discharge of a single vesicle or a single shutter action. Recent reports have pointed to a remarkable heterogeneity of the quantum in the mouse and frog neuromuscular junction^{11,12} and in some cases subunits are apparent. In this investigation, evidence is provided from the frog neuromuscular junction that the 'quantum' has subunits.

Spontaneous depolarisations of the postsynaptic cell were first observed in the neuromuscular junction of the frog¹³. Since the amplitude histograms of these depolarisations were well described by a single Gaussian curve they were consequently^{14,15} considered to be due to the liberation of the smallest possible amount of transmitter substance and thus named quanta, single units, and so on. In subsequent experiments (for example, refs 7 and 8) it was found that evoked transmitter release occurs in multiples of these unit packages.

In the present investigation conventional intracellular recording techniques were used to monitor spontaneous miniature endplate potentials (m.e.p.ps) from small muscle cells (20–40 μm diameter) of frog cutaneous pectoris muscles (*Rana temporaria* and *Rana esculenta*) at room temperature.

To rule out systemic errors in measuring the signal amplitudes two independent procedures were used in most experiments. Both involved electronic computing devices (with fast AD converters) which were programmed to recognise the typical signal shape. In the on-line version (PDP8E) a 1-mV signal at the cell corresponded to 231 digital points (thus measuring in steps of $\approx 4 \mu\text{V}$); peak amplitudes were obtained by gliding averaging of the signal trace. In the off-line (PDP10) version, signals were stored on analogue tapes (10 kHz) and later peak amplitudes were evaluated by fitting an idealised theoretical curve to each signal. Both methods produced the same results. Class width and starting point of the histograms were chosen such that the subunits were most clearly visible. Records were carefully investigated for a change in the average amplitude of the m.e.p.ps with time. In the present investigation only stable periods were used for further examinations.

Figure 1 shows amplitude histograms of two different cells. The overall appearance of the distributions is normal. Peaks are, however, apparent at regular distances from one another (dots). To analyse these peaks, a statistical test was adopted which is basically binomial and similar to the methods in use for the classic quantum analysis^{8,10}. It is assumed that there is a constant number of independent subunits (n_v) in each 'active site' (see below), each one having the same probability (p_v) of being discharged when the site is activated. Subunit size (SU = mean amplitude, b = coefficient of variation) is similar in each 'active site' and subunits sum linearly. The size of the subunits as well as the binomial parameters and the predicted curves were estimated by two means.

Method A: Estimation of SU from the amplitude histogram by eye; the multiples have to fit as many as possible of the visible peaks and the first theoretically possible SU must start at 0 mV. The binomial parameters n_v and p_v were then estimated using conventional methods¹⁰. To compare the observed and expected distributions the 'geometrical' method described in detail by Boyd and Martin⁸ was used. b was chosen to give the best fit.

Method B: A non-linear least-squares fit¹⁶, which takes into account all the above assumptions, was used in a computer program to find values for SU , b , n_v and p_v which would provide the best fit to the observed histogram.

Figure 2 shows observed and fitted curves for two

Fig. 1 Intracellular amplitude histograms of spontaneous m.e.p.ps recorded from two different muscle fibres. The total number of observations was 512 in a and 510 in b. Resting membrane potential was 85 mV and 65 mV, respectively. Note peaks at regular distances (dots). The amplitude of the subunits (SU) was estimated using method A. SU is 0.178 mV in a and 0.160 mV in b.

experiments. In all cases there is a good fit thus providing evidence for the existence of subunits. In most experiments (14 out of 18), subunits were apparent, whereas in others no evidence for subunits could be obtained.

Theoretically, the observed subunits could be produced at both the pre- and postsynaptic level or even in the synaptic cleft. Any such mechanism, however, is less plausible than the simple explanation, that spontaneous transmitter release occurs in multi-package units.

In electron micrographs, gatherings of synaptic vesicles are seen at the regularly spaced 'active zones'^{15,17,18}, and it seems that there is a strictly ordered double row with a total of about 10–30 vesicles at each 'active zone'¹⁷. From simultaneous measurements of individual quantal discharges with three micro-electrodes, it has been inferred that spontaneous release of transmitter occurs exclusively at discrete sites ('active sites'), which most likely correspond to the 'active zones'¹². Recent statistical estimations of the number of 'units in the nerve terminal capable of (quantal) release (n)' indicate that in the frog neuromuscular junction, n is small (about 1 per micron length of the nerve terminal). These numbers roughly correspond to the number of 'active zones' in the activated length of the nerve terminal, which in turn suggests that not more than one quantum is discharged at each 'active zone'.

The numbers of subunits in the amplitude histograms were found in several experiments to be between 2 and 15 which are somewhat less than, but still in accord with, the number of vesicles lined up in an 'active zone'. Considering the evidence for a special function of the 'active zone'^{10,12,17}, therefore, we find it plausible that a quantum might be due to the simultaneous discharge of several or all vesicles in one 'active zone'. No temporal resolution of subunits has as yet been observed during a quantal discharge, so a mechanism must be postulated which triggers release from several vesicles virtually simultaneously. In Fig. 2, at some peaks observed frequencies deviate from the expected ones (for example, Fig. 2a, second and third peak of the theoretical distribution). Such deviations merely violate the simple binomial assumption. Indeed, it is more realistic to assume a threshold mechanism such that all vesicles 'available' at an active site are released ($p_v=1$), n_v is changing in time and is different from site to site. The number of subunits observed in the amplitude distributions then shows the range in n_v .

Since the coefficient of variation (b) of the subunits is very small, the releasable transmitter content of individual vesicles must be very similar.

Based on amplitude measurements of a large number of spontaneous m.e.p.ps and application of a statistical test, evidence is presented that quanta consist of about 2 to 15

Fig. 2 Observed and fitted amplitude distributions for spontaneous m.e.p.s. from two experiments. Method B was used in *a* and method A in *b*. The amplitude of the subunit (*SU*) was 0.0768 mV in *a* and 0.2177 mV in *b*. The coefficient of variation was 0.11 (*a*) and 0.05 (*b*). The binomial parameter *n*, was calculated as 8 (*a*) and 10 (*b*). The total number of observations (*N*) was 489 (*a*) and 507 (*b*). The predicted curve starts at 0 mV. Note deviation from the observed distribution especially in *a* (for example, second and third peak of the predicted distribution).

subunits. It is proposed that the quantum is due to the simultaneous discharge of several transmitter quantities at one site. Taking into account other evidence^{10,12,17}, it is postulated that the 'active zone' is a functional unit. Its activation leads to the simultaneous discharge of synaptic vesicles lined up there: this creates a single quantum.

Some of the equipment used in this study was provided for A.W. by the Austrian Fonds zur Förderung der Wissenschaftlichen Forschung.

Light-activated GTPase in vertebrate photoreceptors

In studies of the regulation of cyclic GMP levels by light we found that rod outer segment disk membranes contain a cyclic GMP phosphodiesterase (PDE) with a molecular weight of 240,000, whose activation depends on the photoisomerisation of rhodopsin in the presence of a nucleoside triphosphate¹⁻³. We report here an additional light-dependent enzyme activity, the hydrolysis of GTP to form GDP and inorganic phosphate, which functions as another enzymatic component in the regulation of photoreceptor guanosine nucleotide levels by light. This GTPase has the action spectrum of rhodopsin and is half-maximally activated by bleaching only one in 2,000 rhodopsins. The enzyme has an apparent *K_m* for GTP of 0.5 μ M. GTPase activity can be quantitatively removed from the disk membranes and the activity can be fully restored to the disk membranes by a partially purified heat labile protein with an apparent molecular weight of 32,000.

In studies of the activation of photoreceptor cyclic GMP PDE by light and nucleoside triphosphate¹⁻³, we attempted to catalogue all possible reactions of the phosphoryl donors (γ -³²P)GTP and (γ -³²P)ATP. We have observed that between 0.01 and 5 μ M nucleoside triphosphate, light can stimulate the hydrolysis of GTP, but not ATP, in frog (*Rana catesbiana*) outer-segment disk membranes.

The photoreceptor GTPase shows remarkable sensitivity to light; half-maximal activation is observed when only 1 in 2,000 rhodopsins is photoisomerised (Fig. 1). In our conditions (only 0.05% of rhodopsin photoisomerised, 0.5 μ M GTP and 1.2 mg per ml protein), 95% of the radioactivity from (γ -³²P)GTP is found as inorganic phosphate within 10 min and less than 3% covalently labels disk membrane protein (as monitored in sodium dodecylsulphate (SDS)-polyacrylamide gel electrophoresis). The sensitivity of this GTPase to light is identical to that reported for the light-activated photoreceptor PDE (ref. 3).

We next examined the dependence of the activation of GTPase on the wavelength of the exciting light. We arranged conditions where we could compare the efficacy of GTPase activation by equal numbers of photons at wavelengths ranging from 425 to 600 nm. This action spectrum for GTPase corresponds perfectly to the absorption spectrum of the rod photopigment rhodopsin (Fig. 2).

The light activation of photoreceptor GTPase can be accomplished in one of two ways. We can either randomly photoisomerise a small fraction of the total disk membrane rhodopsins (with a flash of light) or we can produce an activation of more than sixfold by adding a 1% admixture of fully photoisomerised membranes to a reservoir of a fully dark-adapted, unwashed suspension of disk membranes. This activation by the phenomenon of mixing was also observed for the light-activated photoreceptor PDE³. This activation is seen in conditions where the contribution of GTPase activity by the 1% admixture is negligible (see Table 1). It is not yet clear whether activation by mixing depends on the fusion of vesicles containing bleached rhodopsin with dark membranes, or whether the bleached material contributes some soluble cofactor in the activation sequence.

The light-activated GTPase activity can be quantitatively removed from the disk membranes by lysing unilluminated rods in 1.0 mM EDTA (pH 7.0), and collecting the disk membranes by centrifugation (35,000 r.p.m., Beckman SW56 rotor, 1 h,

Table 1 Light activation of GTPase by a flash of light or by the combining of dark and fully bleached membranes

	GTPase
0.05% bleached* membranes	300
Dark membranes	48
Dark membranes plus fully bleached membranes† (99 : 1 protein)	302
Fully bleached component of above mixture	0

GTPase activities are expressed as pmol GTP hydrolysed per mg protein per min. GTP assays were done in the conditions stated in Fig. 1.

*0.05% 'bleached' membranes are disk membrane suspensions in which 0.05% of the rhodopsin is photoisomerised.

†The bleached component of the mixture was washed (by sedimentation and resuspension) three times before full illumination with 100 mM Tris-HCl (pH 7.4) containing 5 mM MgSO_4 and 1 mM dithiothreitol. This washing procedure removes 90% of the GTPase activity.

4 °C). These disk membranes, after one additional wash in the same buffer, showed no GTPase or PDE activities. Both PDE and GTPase activities can be restored to the washed disk membranes by addition of light, 5 mM Mg^{2+} and the supernatant obtained by centrifugation of the lysed rods. This supernatant alone does not show GTPase activity. The supernatant was subsequently applied to a Sepharose 6B column which was equilibrated and eluted with 10 mM Tris (pH 7.5) containing 5 mM MgSO_4 , 1 mM dithiothreitol and 50 mM KCl. Column fractions were assayed by recombination with the washed and illuminated disk membranes described above. A single peak of GTPase activity is associated with a heat-labile molecule which does not display PDE activity and which gives a sharp (Coomassie blue positive) band with an apparent molecular weight of 32,000 in SDS-polyacrylamide gel electrophoresis⁶.

Fig. 1 Light activation of GTPase as a function of the extent of rhodopsin bleaching. Varying degrees of rhodopsin photoisomerisation were obtained by exposing disk membrane suspensions to attenuated (neutral density filtered) light for various times. The filter array was calibrated to permit half-maximal activation with a 30-s exposure. The % rhodopsin photoisomerised was directly measured in 1% hexadecyltrimethylammonium bromide for bleaches in excess of 5% and linearly extrapolated to determine fractional % bleaches accomplished at shorter exposure times. GTPase activity was measured (37 °C at pH 7.4) by the method of Neufeld and Levy⁴ using 0.5 μM (γ - ^{32}P)GTP with specific activity of 20 Ci mmol^{-1} in a reaction volume of 100 μl containing 90 μg of disk membrane protein. Activities are expressed as pmol GTP hydrolysed per mg protein per min. Alternatively, GTPase was assayed by measuring the formation of GDP from (β , γ - ^{32}P)GTP with descending thin-layer chromatography⁵. Rod outer-segment disk membranes were isolated from *Rana catesbiana* by sucrose flotation³. All manipulations and GTPase assays (except intentional illumination) were performed in infrared light using image converters³.

We emphasise that the range of GTP concentrations over which light activation is observed is from 0.01 to 5 μM GTP. The K_m for the light-activated reaction is approximately 0.5 μM ($\pm 0.4 \mu\text{M}$) GTP. The maximum velocity achieved by the light-activated GTPase is approximately 500 pmol GTP hydrolysed per mg protein per min. Above 5 μM GTP, however, no light activation of GTPase is seen but an additional GTPase activity is observed which has a K_m of 90 μM GTP and a V_{max} of 12 nmol GTP hydrolysed per mg protein per min.

Fig. 2 Action spectrum of light-activated GTPase. Points represent the fraction of highest (A_{500}) GTPase activity above basal. The highest activity observed (at 500 nm) was 80% of maximum possible activation by light. (Basal activity was 30 pmol GTP hydrolysed per mg protein per min). The solid curve is the absorption spectrum of rhodopsin in 1% hexadecyltrimethylammonium bromide. Exposure of disk membranes to equal photon numbers of monochromatic light was accomplished using a light-shielded Gilford 2000 spectrophotometer. The sample holder and photomultiplier were replaced with a camera shutter positioned after the exit slits to allow timed flashes of light. Frosted glass placed in front of the shutter aperture provided a uniformly diffuse source of light. A 100- μl membrane sample was contained in a self-masking cuvette with a 5-mm path length, which was situated after the frosted glass. The intensity of the tungsten lamp at each wavelength was first measured with a YSI radiometer. The intensity profile was used to compute a sample exposure time to normalise photon number at each wavelength. GTPase activities were assayed using the conditions described in Fig. 1.

It is not yet clear whether the high- K_m GTPase activity resides in a second enzyme or reflects changes in the low- K_m enzyme which are brought about by higher (possibly non-physiological) levels of GTP. Interpretation of the physiological roles of the light-activated (low K_m) and non-light-activated (high K_m) GTPase will depend on further studies of GTP concentration *in vivo*.

Finally, we are intrigued by the extraordinary similarity in the light requirements shown by both the GTPase and PDE of vertebrate outer-segment disk membranes. This similarity embraces activation both by a flash of light and by the phenomenon of mixing, suggesting that these enzymes may be functionally, if not topologically, linked. After submission of this manuscript we were informed of a report of similar findings published in the abstracts of the 21st Biophysical Society meeting⁷.

Salt-sensitive *in vitro* protein synthesis by a moderately halophilic bacterium

EXTREMELY halophilic bacteria, such as *Halobacterium cutirubrum*, grow only in high NaCl concentrations (2.5–5 M) and have very high (5 M or higher) internal concentrations of salts, mainly KCl^{1,2}. The ribosomes and protein-synthesising systems of these organisms seem especially adapted to function in such concentrations³. In contrast, moderately halophilic bacteria, such as *Vibrio costicola*, grow over a much wider range of NaCl concentrations (at least 0.5–3.5 M)⁴. In *V. costicola*, though not necessarily in all moderate halophiles, the cell-associated monovalent cations are at least as concentrated as those of the external medium. For example, cells growing exponentially in medium containing 1 M NaCl and 0.008 M KCl can have internal Na⁺, K⁺, and NH₄⁺ concentrations of about 0.6, 0.7 and 0.4 M respectively, as well as 40 mM Mg²⁺ (ref. 5 and our unpublished results). Ribosomes from *V. costicola* differ from those of both extremely halophilic and non-halophilic bacteria in their ability to maintain a 'standard' sedimentation pattern (30, 50 and 70S) over a wide range of salt concentrations. This pattern is not changed by the NaCl concentration in which the cells are grown⁶. Such properties, however, do not really tell us how well the ribosomes function at different salt concentrations. Studies of *in vitro* protein synthesis, reported here, suggest that ribosomes may function at much lower salt concentrations than measurements of total cell-associated ions indicated to be present in the cell.

Extracts were prepared from cells grown in medium containing 1 M NaCl, washed, and suspended in mixtures of NaCl, KCl, NH₄Cl and MgCl₂ approximating the cell-associated concentrations of these cations. Cells were broken by osmotic lysis or by grinding with alumina. After centrifugation at 30,000g for 30 min to remove intact cells and membrane fragments, the supernatants (S-30) were incubated with the ingredients used to demonstrate *in vitro* protein synthesis in other bacterial extracts (see legends to Figs 1 and 2), but with the final salt concentrations adjusted to that in which the cells were broken. No activity was found, as measured by incorporation of radioactive amino acids into trichloroacetic acid-precipitable material. But, if no salt was added to the assay mixture other than that contained in the extract (final concentration about 0.2 M) protein synthesis occurred. If the concentration of any salt was increased, activity fell. At concentrations of 1 M or higher, no activity could be measured.

Figure 1 shows the effects of various concentrations of salts of monovalent cations and MgCl₂ on poly U-dependent phenylalanine incorporation. Figure 2 gives comparable results for incorporation using 'endogenous messengers'—that is, incorporation of a mixture of ¹⁴C-labelled amino acids from a *Chlorella* hydrolysate. In both systems activity was highest in NH₄Cl, followed by KCl, then NaCl. Optimal activities occurred in 0.1–0.2 M salts, and higher concentrations were inhibitory. This was especially noticeable in the effects of NaCl on the 'endogenous' system. Magnesium ions were needed for activity, maximal activity being reached at about 18 mM Mg²⁺ in both systems.

We considered the possibility that high concentrations of monovalent cations inhibited protein synthesis because they were displacing the essential divalent cation, Mg²⁺. If this were so, it should be possible to overcome the inhibitory effect of the former by increasing the latter. In both systems, however, increasing the MgCl₂ concentration two- or fivefold (from 20 mM) did not reverse the inhibition caused by higher concentrations of the other salts (up to 1 M). Higher concentrations of Mg²⁺ were just as inhibitory in the presence of higher as in lower concentrations of the other salts.

One of the problems with establishing a protein synthesising system in a 'new' bacterium, is showing that the measured incorporation represents polypeptide synthesis. This was shown by the following findings. Incorporation is energy dependent. In the absence of poly U phenylalanine incorporation was reduced by 90%, and ¹⁴C-leucine was incorporated to about the same extent as phenylalanine. Leucine incorporation was not stimulated by poly U. Treatment of the system with ribonuclease A (Sigma, 40 µg ml⁻¹ in assay mixture) abolished all activity. Chloramphenicol (15 µg ml⁻¹) and puromycin (25 µg ml⁻¹) strongly or completely inhibited activity. Aurintricarboxylic acid (105 µg ml⁻¹) inhibited incorporation in both the poly U-dependent

Fig. 1 Effects of NaCl (□), KCl (△), NH₄Cl (○) and MgCl₂ (insert) on the poly U-dependent ¹⁴C-phenylalanine incorporation. *V. costicola* cells, grown in 1 M NaCl, were broken by grinding with twice the wet cell weight with alumina. After centrifugation at 30,000g for 30 min to remove whole cells and membrane fragments, small volumes (1–2 ml) of the extracts were dialysed with rapid stirring for 1 h against 1–2 l of a solution of 100 mM NaCl, KCl, or NH₄Cl, depending on the salt to be studied, plus 20 mM MgCl₂ and 10 mM Tris-HCl, pH 7.6. This dialysed extract was then centrifuged at 30,000g for 30 min and the resulting supernatant was termed the S-30 extract. 90 µl of the S-30 extract was incubated with 210 µl of the reaction mixture so that the final concentrations were: 15 mM phosphoenol pyruvate; 2 mM adenosine triphosphate; 1 mM guanosine triphosphate; 18 mM MgCl₂ (or as indicated, insert); 30 µg ml⁻¹ pyruvate kinase; 50 mM Tris-HCl, pH 7.6; 7.5 mM reduced glutathione; 9.6 µM ¹⁴C-phenylalanine (522 mCi mmol⁻¹); 270 µg poly U; and 100 mM NH₄Cl, KCl, or NaCl, or the concentration as indicated. The reaction was incubated at 30 °C and 50 µl aliquots taken at 0, 2, 4, 6, and 8 min. The aliquots were precipitated with 3 ml of cold 5% (w/v) trichloroacetic acid, heated at 90 °C for 20 min, then collected onto 0.45-µm filters (Millipore). The filters were dried and counted in a liquid scintillation counter with 5 ml of Scintiverse (Fisher Scientific). An activity of 100% represents 22.2 pmol of phenylalanine incorporated per min per A₂₆₀ unit of the S-30 extract.

Fig. 2 Effects of NaCl (○), KCl (△), NH₄Cl (□) and MgCl₂ (insert) on the amino acid incorporation dependent on 'endogenous messenger'. *V. costicola*, grown in 1 M NaCl, cells were lysed osmotically by suspending the cell pellets in buffer containing: 200 mM KCl; 10 mM Tris, pH 7.6; and 5 mg ml⁻¹ lysozyme. After 2–3 min incubation on ice, the ionic concentration and composition was restored to: 100 mM KCl; 10 mM Tris, pH 7.6; and 18 mM MgCl₂. S-30 extracts were prepared and dialysed as in Fig. 1. The assay conditions are as in Fig. 1 except that poly U and ¹⁴C-phenylalanine were omitted and ¹⁴C-labelled *Chlorella* hydrolysate (54 mCi per mAtom of carbon) was substituted. The values are expressed as % of maximum activity, maximum activity being 300 c.p.m. per min per A₂₆₀ unit.

and the endogenous system. Analysis of the end products of ¹⁴C-phenylalanine incorporation by the method of Pestka *et al.*⁷ showed that 58% was in the form of diphenylalanine, 25% in the form of triphenylalanine, and 17% in the form of higher oligo- or polypeptides.

Salts had a different effect on the stability of the protein synthesising system than on its activity (Table 1). Concentrations of all monovalent salts which inhibited protein synthesis could stabilise the system. Usually, the system was more stable at lower temperatures. Only in the highest NaCl concentration (2 M) did rapid inactivation of the system occur (not shown in Table 1). We cannot assign the effects of the salts to any specific component of the protein synthesising system, but it has been shown that certain salts

Table 1 Effects of Na⁺, K⁺, and NH₄⁺ chlorides on the stability of the poly U-dependent incorporation of ¹⁴C-phenylalanine

Salt	30 °C	<i>t</i> _{1/2} values (min)		3 °C
		20 °C	20 °C	
0.1 M NH ₄ Cl	22	160	510	
1.0 M NH ₄ Cl	63	∞	∞

400 μl of the S-30 extract, dialysed against 100 mM of the appropriate salt was incubated with solid salt to raise the concentration to the desired level. Aliquots of 90 μl of this mixture were removed at various times and assayed as described in Fig. 1 except that for the 1 M salt concentrations no monovalent ions were added to the reaction mixture. This resulted in a final concentration of 0.3 M salt. The *t*_{1/2} is the time required for the extract to lose half of the original activity. The ∞ symbol indicates that the extract lost no activity over the test period (usually 8 h).

have different effects on the stability and the activity of individual enzymes of halophilic bacteria^{2,8}.

It is very difficult to predict the state of ions in the cytoplasm of a cell from knowledge of the total concentration alone. Certain physiological functions might provide a better estimate of the actual internal state of these ions. It is probably significant that many of the internal enzymes of the halobacteria function better in KCl than in NaCl^{2,8}. It is more significant that protein synthesis, a process dependent on many enzymes and on the proper configurations of ribosomes and their interactions with mRNA, also functions in the conditions that are suggested to exist in these cells by total ionic analysis. This is not so for *V. costicola*. Rather, protein synthesis occurs in much lower salt concentrations than those found in the cell as a whole. Protein synthesis would be completely inhibited by the salt concentrations found in the bacteria, if all were free in the cytoplasm. Our results suggest that they are not free, but rather that they are sequestered within the cell. Possibly Mg²⁺ is bound to the cell envelope (optimum Mg²⁺ level for protein synthesis is less than half of total cellular concentration). Many bacterial envelopes can bind divalent cations⁹. It is less easy to envisage a binding site for the monovalent cations. A binding of such cations to envelopes has been reported for other moderately halophilic and non-halophilic bacteria, however (discussed in ref. 5). We are investigating this possibility for *V. costicola*.

Carbon dioxide governs the oxygen affinity of crocodile blood

OXYGEN affinity of haemoglobin inside red blood cells is decreased to a level where oxygen unloading can proceed at sufficiently high partial pressures in the tissue capillaries. This adaptation of oxygen affinity is accomplished mainly by the interaction of haemoglobin with intraerythrocytic phosphates¹. These comprise 2,3-diphosphoglycerate (DPG) in most mammals, ATP and GTP in fish², and *myo*-inositol pentaphosphate (IP₅) in mature birds^{3–5}. No haemoglobin system has been described in higher vertebrates which is devoid of functional interaction with the respective intracellular phosphates. Recently, however, Sullivan⁶ has questioned the role of phosphates for the control of oxygen affinity in crocodile

red cells (ATP and inorganic phosphate have been identified^{3,7,8}). He remarks that "the substance regulating oxygen affinity in alligators is very efficient, but unknown". We show here that the oxygen affinity of haemoglobin from a member of the order crocodiles (*Crocodylus porosus*) is not affected by any of the regulating allosteric cofactors known with the exception of molecular CO₂ and protons.

A specimen of *C. porosus*, about 5-yr-old, was anaesthetised with Rompun and Kataral and blood obtained by heart puncture. Red cells were washed in saline and lysed by addition of distilled water. The ghosts were removed by centrifugation. The clear supernatant was passed over Sephadex G-25 columns at 4 °C equilibrated with Tris buffer pH 8.1 to remove all phosphates, and subsequently dialysed against 0.1 M NaCl. The oxygen affinity of haemoglobin solutions was determined as described earlier⁹.

The partial pressure of oxygen at which purified haemoglobin solution is half saturated with oxygen (P_{50}) was 3.9 Torr (20 °C, pH 7.3) and increased to 28.8 Torr on addition of CO₂ ($p\text{CO}_2 = 40$ Torr, pH 7.3). This value is very near to the one found in whole blood ($P_{50} = 30.3$ Torr at 20 °C, extracellular pH 7.47, $p\text{CO}_2 = 40$ Torr). At more alkaline pH the effect of CO₂ on P_{50} is even more pronounced (Fig. 1). Note that the concentration of ATP was low in crocodile erythrocytes (0.6 mM) and that UTP, CTP, ITP, GTP and DPG could not be detected enzymatically¹⁰ or by thin-layer chromatography². Apart from ATP the following phosphates were

tested with respect to their possible influence on P_{50} of haemoglobin solutions: IP₅ prepared from chicken blood¹¹, DPG, fructose-1,6-diphosphate, and cyclic AMP, each used in a 10–20-fold excess of phosphate over Hb₄. None of these led to a significant shift of P_{50} . Similarly, inorganic phosphate (0.1 M) had no effect on the oxygen affinity of crocodile haemoglobin. Apart from CO₂ only protons led to heterotropic interactions with the oxygen binding: $\Delta \log P_{50}/\Delta \text{pH} = -0.43$ in the alkaline range (Fig. 1). When the change in pH was produced by varying $p\text{CO}_2$ at constant HCO₃⁻ concentration $\Delta \log P_{50}/\Delta \text{pH}$ increased to -0.66 due to the additional action of CO₂ on P_{50} . Cooperativity of oxygen binding was not significantly influenced by CO₂: the exponent n in Hill's equation¹² was 2.1 in the absence and 2.0 in the presence of CO₂.

The question arises then as to how this remarkable effect of CO₂ on the oxygen affinity of crocodile haemoglobin can be explained on a molecular basis. As reptile haemoglobins polymerise in certain conditions^{6,13} it is conceivable that the action of CO₂ leads to increased aggregation with consecutive decrease in oxygen affinity. Gel filtration experiments on Sephadex G100 columns operated with *bis*-Tris buffer pH 7.3 at 20 °C yielded two components in equal proportions, one which is probably 'octameric' (apparent molecular weight 110,000) and one 'tetrameric' species (apparent molecular weight 43,000). This proportion was very much the same when the experiment was carried out with bicarbonate buffer equilibrated continuously with CO₂ so to give the same pH and ionic strength. Furthermore, oxygen binding curves of the isolated components showed that CO₂ produced the same decrease in oxygen affinity in the 'octameric' and in the 'tetrameric' pigment as in the unfractionated haemolysate. Additional control experiments on Sephadex G100 were carried out to check that the respective components had not interconverted during the oxygen binding experiments. Both the 'octameric' and the 'tetrameric' component appeared as one major band in isoelectric focusing experiments with isoionic pH values of 7.24 and 7.26, respectively.

Thus we conclude that a reversible aggregation-dissociation phenomenon is not the cause for the CO₂-induced decrease in oxygen affinity of crocodile haemoglobin. Most likely the formation of oxygen-linked carbamate compounds is responsible for the observed effects, qualitatively similar to what is found in human haemoglobin, where more carbamate is present at the terminal α -amino groups in the deoxy- than in the oxy-structure. If the same residues mediate the carbamate formation in crocodile haemoglobin, our data suggest that the carbamate equilibrium constant as well as the change of the carbamate equilibrium constant when the haemoglobin binds or releases oxygen must be higher than even in the β -subunits of human haemoglobin, where most oxygen-linked carbamate is being formed^{9,15}. The negatively-charged carbamate itself could stabilise the deoxy-structure and de-stabilise the oxy-structure of crocodile haemoglobin by secondary interactions with positively-charged residues. If such interactions lead to structural transitions of the quaternary structure it may be possible to observe changes in the absorption spectrum as, for example, in certain fish haemoglobins at different pH values¹⁶. Difference spectra in the Soret range obtained on crocodile haemoglobin in the absence and presence of CO₂ ($p\text{CO}_2 = 100$ Torr) gave no indication of such transitions, however.

Whatever the exact molecular mechanism of the strong antagonism between CO₂ and oxygen binding turns out to be, it is significant that this particular interaction, which must have appeared quite early in the evolution of haemoglobin function in vertebrates^{14,17}, has been explored very efficiently in a member of the order *Crocodylia* which possesses haemoglobins with a high intrinsic oxygen affinity and only little intra-erythrocytic phosphates. In situations where the animal moves about very quickly and therefore liberates CO₂ from the tissues, the antagonism between CO₂ and oxygen binding should be very efficient in aiding oxygen release from the blood.

We thank Dr Wiesner from the Tierpark Hellabrunn,

Fig. 1 Plot of $\log P_{50}$ against pH of crocodile haemoglobin in the absence (○) of CO₂ and at a $p\text{CO}_2$ of 40 Torr (●) at 20 °C. Hb concentration 120 μM haem; buffers: 50 mM *bis*-Tris-100 mM NaCl in the absence of CO₂ (total ionic strength 0.150) and bicarbonate-NaCl buffer in the presence of CO₂, 150 mEq l⁻¹. pH was also varied by changing $p\text{CO}_2$ at constant bicarbonate concentration (▲). Blood P_{50} was determined by means of the Lex-O₂-Con apparatus at 20 °C, $p\text{CO}_2$ 40 Torr and extracellular pH 7.47 (⊗). The dotted lines were obtained from similar experiments on human haemoglobin in the absence (lower) and presence (upper) of CO₂⁹.

München, for blood samples, Mrs U. Engels for technical assistance and to Dr G. Gros for helpful comments.

Note added in proof: Oxygen binding to haemoglobin from another crocodile species, *Caiman crocodylus*, exhibits the same strong interaction with molecular CO_2 , but none with ATP.

Hapten-induced allosteric transition in the light chain dimer of an immunoglobulin

THE dimer of immunoglobulin light chains (L_2) was shown by X-ray crystallography to be structurally homologous to the native immunoglobulin Fab fragment (HL) (refs 1–3). This led to the suggestion that L_2 is a model for a primitive antibody¹ and for the T-cell receptor^{2,23}. In L_2 315 (from the mouse myeloma protein MOPC 215) functional homology was also implicated in that both L_2 and HL bind the same nitroaromatic haptens with similar fine specificity^{4,5}. We have considered the possibility that this homology extends also to hapten-induced conformational changes and that studies with L_2 will yield information on the nature of such processes in immunoglobulins. L_2 315 constitutes a particularly good model system for such studies as it binds two hapten molecules per dimer at symmetry-related sites^{4,5}. It is thus possible to monitor the conformational effects of the first binding hapten through the mode of interaction with the second, as revealed by the shape of the saturation curve⁶. We report here that dinitrophenyl-lysine (DNPL) and its fluorescent analogue nitrobenzoxadiazole-alanine (NBDA) (ref. 7) both display sigmoidal binding curves, implying positive cooperativity in their interaction with L_2 315. This observed cooperativity is shown to arise from a hapten-induced conformational transition which may be described by the allosteric model⁶. We propose that this allosteric transition involves changes in the relative position of the chains in L_2 , lending support to suggestions^{8,9} that a similar process occurs in the structurally homologous intact immunoglobulin. These findings are, therefore, relevant to the question of antigen-triggered effector functions of antibodies through an allosteric mechanism^{8,10–12}.

The difference spectra observed on addition of hapten to L_2 315 are shown in Fig. 1a and b. Each hapten displays its characteristic difference spectrum which varies little throughout the titration as is particularly emphasised in the well defined isosbestic points for NBDA. This strongly suggests that the two sites on L_2 315 are identical with respect to hapten binding. Accordingly, any model used to account for the observed cooperativity should be symmetric, in line with the previously suggested local symmetry around the binding site of L_2 315 (ref. 5).

The hapten occupancies (calculated from the absorption changes) were plotted against hapten concentration (Fig. 2). For both haptens the binding curve is sigmoidal, the effect being more pronounced with NBDA. For this hapten equi-

Fig. 1 Difference spectroscopic titrations in which *a*, 4-(α -N-L-alanine)-7-nitro-benz-2-oxa-1,3-diazole (NBDA)⁷, and *b*, ϵ -N-2,4-dinitrophenyl-L-lysine (DNPL), are added to mildly reduced and alkylated L_2 315⁴ in 0.01 M sodium phosphate buffer pH 7.4 with 0.15 M NaCl (PBS). ΔA is the change in hapten absorption on binding to L_2 ($\Delta A = A_{\text{bound}} - A_{\text{free}}$). Spectra were taken on a double beam Cary 118 spectrophotometer in rectangular quartz cuvettes of 0.437 cm pathlength at 4 °C. Equal aliquots of hapten solution were added to a cuvette containing the protein solution and to a reference cuvette containing an exactly equal volume of buffer. The minor contribution of protein absorption below 320 nm was corrected electronically. Initial L_2 concentration was 6.0×10^{-5} M sites (assuming 2 sites per protein molecule, and $\epsilon_{280} = 60,000 \text{ M}^{-1} \text{ cm}^{-1}$ for the dimer).

brum dialysis measurements were also performed and the points were found to lie on the same binding curve (Fig. 2). The origin of the observed sigmoidity is therefore thermodynamic and not spectroscopic—that positive cooperativity occurs in the binding of hapten. The data were analysed according to the Adair¹³ formalism as described in Table 1.

The underlying mechanisms of the observed positive cooperativity may be one of the following: (1) the first bound hapten exerts a direct attractive interaction on the second; (2) hapten binding is coupled to a chain-dissociation equilibrium of the form $L_2 \rightleftharpoons 2L$ (refs 14, 15); (3) hapten binding is linked to an allosteric conformational transition in L_2 . Since the sites on L_2 315 are probably no more than 12 Å apart⁸, direct contact interaction between haptens is possible. But there are strong arguments against it, which are: first, from the chemical nature of the ligands no mutual attraction is expected, particularly not for the negatively charged NBDA; second, attraction between identical ligands would be fortuitous and is unlikely to occur in two different cases; and third, direct hapten interaction is expected to lead to spectral asymmetry because the first hapten interacts only with protein residues while the second hapten also interacts with the first. The possibility of chain dissociation at the L_2 concentration studied (3×10^{-5} M) was ruled out by a series of sedimentation

Table 1 The best fit parameters for the curves in Fig. 2 according to different models

Hapten	Intrinsic Adair constants (M^{-1})	n_H	λ (nm)	$\Delta\epsilon_\lambda$ ($cm^{-1}M^{-1}$)	L	Intrinsic MWC constants (M^{-1})	$c = K_T/K_R$
NBDA	$K_1 = 5.0 \times 10^2$ $K_2 = 5.6 \times 10^4$	1.83	464 515	-12400 +6800	110	$K_T = 0$ $K_R = 5.6 \times 10^4$	0
DNPL	$K_1 = 3.5 \times 10^3$ $K_2 = 1.4 \times 10^4$	1.33	354	-4500	110	$K_T = 2.9 \times 10^3$ $K_R = 6.7 \times 10^4$	0.043

The Adair formalism¹³ makes no mechanistic assumptions other than that L_2 has two initially identical sites, and it enables us to calculate their apparent consecutive binding constants, K_1 , K_2 (see ref. 14). The binding curves are fitted according to this formalism assuming a constant value of $\Delta\epsilon$ throughout the titration (see text). λ is the wavelength at which $\Delta\epsilon$ is measured. n_H is the slope of the Hill plot (insert of Fig. 2) at half saturation, where $\log [R/(N-R)] = 0$. It may be calculated as $n_H = 2/[1 + (K_1/K_2)^{1/2}]$, and for positive cooperativity $1 < n_H \leq 2$ (ref. 14). The MWC model⁶ assumes an equilibrium between two conformations of the hapten-free protein $T_0 \rightleftharpoons R_0$ ($L = T_0/R_0$) which bind the hapten with different association constants K_T , K_R ($c = K_T/K_R < 1$). The MWC parameters were calculated from the Adair constants according to ref. 14. Both exclusive binding ($K_T = 0$) and non-exclusive binding ($K_T > 0$) are mathematically equivalent to the Adair scheme and are indistinguishable by parameter fit. Exclusive binding is the simplest as it makes possible calculation of unique values for L and K_R . As L is an attribute of the protein, it should be equal for both haptens. It was found impossible to fulfill this unless non-exclusive binding is assumed either for DNPL or for both haptens. We chose the first possibility thus getting a lower-limit estimate of L . Hapten binding has an appreciable effect on the conformational equilibrium: in the absence of hapten only about 1% is in the R form [$1/(1+L)$] while in the fully saturated protein R amounts to 100% and 83% for NBDA and DNPL respectively [$1/(1+Lc^2)$]. This is in line with the fact that the free energy change in the T to R transition is $\Delta G = -RT \ln(1/L) = 2.8 \text{ kcal mol}^{-1}$, which is comparable to $-RT \ln K_R \sim -6.5 \text{ kcal mol}^{-1}$ for the binding of both DNPL and NBDA.

Fig. 2 Saturation curves of L_2 315 with NBDA: \circ , ΔA at 464 nm; \odot , ΔA at 515 nm and with DNPL; \times , ΔA at 354 nm. R is the average site occupancy by the hapten, calculated as $R = \Delta A/(\Delta\epsilon A_0)$ where A_0 is the molar concentration of L_2 and $\Delta\epsilon = \epsilon_{bound} - \epsilon_{free}$ is the change in the molar extinction of the hapten on binding ($R < 2$). H is free hapten concentration. For NBDA equilibrium dialysis points (\bullet) are also shown. These were measured as described⁶ and concentrations were monitored spectrophotometrically. A parameter fitting nonlinear least square procedure²¹ was used to obtain the values of K_1 , K_2 and $\Delta\epsilon$, as given in Table 1. The solid lines are drawn using these values of the parameters. The broken line is calculated assuming a single association constant $K = 6.3 \times 10^3 M^{-1}$ as previously reported⁴ for the binding of DNPL to L_2 315. It is seen that the difference between the solid and broken lines for DNPL is relatively small which may explain why in a previous (equilibrium dialysis) study with this hapten the cooperativity remained undetected. It should be stressed that in view of the observed cooperativity any previous measurements in which the binding curve was not extensively characterised should be treated with caution. Insert: the saturation points replotted in the form of a Hill plot. N , the number of binding sites per L_2 is 2.0. For NBDA only one titration (ΔA at 515 nm) is reproduced for clarity. The lines are drawn with the same calculated parameters as in the main figure. The slope at $\log [R/(N-R)] = 0$ is denoted n_H and its value is given in Table 1.

measurements in which a value of $S_{20,w} = 3.3 \pm 0.15$ (corresponding to L_2) was found in the concentration range of $6.0 \times 10^{-6} M$ to $2.0 \times 10^{-4} M$ in the presence or in the absence of hapten.

A conformational change induced in L_2 on hapten binding seems therefore to be the most plausible explanation for the observed positive cooperativity. The constancy of spectral effects through the titration strongly supports the notion of a symmetry-conserving process which may be adequately described by the allosteric model of Monod, Wyman and Changeux⁶ (MWC) as detailed in Table 1. The data thus fit a model in which the binding of the first hapten leads to a conversion of both sites from a lower affinity conformation T into a higher affinity conformation R . It is hard to conceive such a transition in terms of local changes limited to a few contact residues only. Rather, the data suggest that hapten binding causes a change in the overall configuration of the dimer which is related to inherent structural and energetic properties of the L_2 molecule as a whole. In view of the evidence that in L_2 haptens interact with both L chains simultaneously^{1,5,16}, it is possible that the hapten participates in the inter-chain interactions that mediate the concerted transition. More specifically, we suggest that hapten binding to one of the sites between the two L chains brings about a symmetry-conserving change in the relative chain position. This transition is associated with a relatively small net free energy change, so that haptens having association constants of the magnitude found here may shift the equilibrium appreciably (see Table 1).

In analogy to the L_2 case, haptens that bind to HL also interact with both chains^{9,17,18}, sometimes enhancing their mutual cohesion¹⁹. Antigen or hapten-induced conformational transitions detected in HL by spectroscopic^{8,10} or kinetic^{12,20} methods, were actually proposed (on the basis of indirect inference) to involve changes of relative chain position^{8,19}. Our results strongly support these suggestions in showing that such changes are energetically feasible in a structural and functional homologue of an immunoglobulin. The inherent structural properties of L_2 which lead to the observed concerted conformational transition probably exist also in HL, since conformation and chain interactions in both were shown to be very similar^{1-3,17}. Direct hapten binding measurements cannot detect conformational changes in HL since it binds only one hapten per two chains (see ref. 12). Kinetic measurements, however, give information on such processes as shown by the chemical relaxation study of hapten-induced conformational changes in another mouse myeloma protein, MOPC 460 (ref. 12). In order to relate the conformational transitions in L_2 and HL, L_2 315 is now also being characterised by chemical relaxation. Preliminary results are in good agreement with

the binding data, suggesting two slowly interconverting conformations which bind the hapten differently.

The changes in relative chain position may also be expressed in a change of the domain interactions, hypothesised to be the primary event in antigen triggering of antibody effector functions through an allosteric transition¹¹. The mechanism proposed here may imply that this transition arises chiefly from mere simultaneous interaction with H and L chains, stemming from inherent structural and energetic properties of HL. It would therefore be relatively antigen-independent, which explains how different antigens, interacting with diverse sites, are able to trigger the effector functions common to all antibody molecules. In any antibody-hapten system, however, the conformational effect will depend on the detailed interactions and will not always be expected to occur.

Two enzymes are required for strand incision in repair of alkylated DNA

THE excision-repair model for DNA repair involves the incision by an endonuclease of the phosphodiester chain adjacent or close to the damage and subsequent excision by an exonuclease of the defective nucleotide(s) (for review see ref. 1). Specific endonuclease for ultraviolet-induced damage¹ and for apurinic sites have been isolated associated with^{2,3}, or without an exonuclease activity (refs 4–6 and J.L. and L. Grossman, in preparation). Another class of enzymes does not incise DNA, but recognises and excises defective bases as uracil in the DNA. Belonging to this class of DNA N-glycosidases, is the enzyme described here which excises 3-methyladenine (3-MeAde) from alkylated DNA. This base excision repair is a preparatory step for the nucleotide excision repair described

Fig. 1 Separation of DNA N-glycosidase from endonuclease for apurinic sites on DNA-Agarose. ●, DNA N-glycosidase; ○, endonuclease for apurinic sites. *M. luteus* ATCC 4698 was grown to late exponential phase¹³ washed in 1 mM EDTA 5 mM mercaptoethanol, 10% glycerol (solution A) containing 10 mM K₂PO₄ (final pH 6.5) and stored at -20 °C. Freshly grown cells (14 g), dispersed in 30 ml of washing buffer were lysed with 50 mg of lysozyme, cooled and sonicated to reduce the viscosity. The resulting solution was slowly titrated to pH 7.7 with 0.1 M KOH and centrifuged for 60 min at 30,000g. The supernatant was loaded on a DEAE-cellulose column (DE 52 Whatman) equilibrated with solution A containing 0.05 M K₂PO₄ (final pH 7.7). Elution was achieved by a linear gradient, the initial concentration was the equilibrating buffer and the limiting one, solution A, containing 0.35 M K₂PO₄ (final pH 7.7). The two activities were not separated. Active fractions were pooled, dialysed against solution A containing K₂PO₄ 0.05 M, final pH 6.7 and loaded on a P-cellulose column (P₁₁ Whatman) equilibrated with the same buffer. Elution was by a KCl linear gradient, 0–0.3 M in the loading buffer. The two enzymes were not separated. Active fractions are pooled and at this step could be stored at -20 °C with a loss of activity less than 10% in 10 months. The last step was chromatography on DNA-Agarose. P-cellulose fractions (2 ml) were diluted with 4 ml of solution A and applied to a DNA-Agarose¹⁴ column (0.4 × 8 cm) equilibrated with solution A containing 0.02 M K₂PO₄ buffer (final pH 7.2). The column was washed with 5 ml of the loading buffer, and eluted with a gradient of KCl 0–1 M in the same buffer (20 ml). Endonuclease for apurinic sites was measured by a modification of the method of Verly and Rassart³ using *E. coli* ³H DNA (3.2 × 10⁷ c.p.m. μmol⁻¹) heavily alkylated with MMS and subsequently heat depurinated. Incubation mixtures (100 μl) contained 10 μmol of K₂PO₄ buffer (pH 7.5), 4 pmol of apurinic DNA and enzyme. After incubation at 37 °C the mixture was chilled at 0 °C and 50 μl of cold calf thymus DNA (0.5 mg ml⁻¹) was added, after 2 min, 200 μl of cold 0.5 M HClO₄ was added¹⁵. After 5 min at 0 °C the precipitate was removed by a 12-min centrifugation at 6,500g and radioactivity measured in Scintigel (Roth). One unit of enzyme liberates 1 nmol of acid-soluble oligonucleotides in 30 min in the above conditions. DNA N-glycosidase was assayed by measuring the release of ethanol soluble 3-MeAde from a calf thymus DNA (4 mg in 2 ml) alkylated¹⁶ with ³H-dimethylsulphate (5 mCi, Amersham). Assay mixtures (100 μl) contained 10 μmol of K₂PO₄ buffer (pH 7.5), 4.58 nmol dimethylsulphate-alkylated DNA (1.5 × 10⁶ c.p.m. μmol⁻¹) and enzyme. After incubation at 37 °C, 50 μl of a solution containing 12.5 μg of calf thymus DNA and 100 μg of bovine serum albumin were added, chilled to 0 °C for 2 min and 300 μl of pre-cooled (-20 °C) ethanol are added. After an additional 5 min at 0 °C the precipitate is removed by a 12-min centrifugation (6,500g, 0 °C) and radioactivity determined. One unit of enzyme liberates 1 pmol of ethanol-soluble alkylated base in 30 min at 37 °C in the above conditions. Ethanol-soluble products are identified as 3 MeAde by chromatography on Dowex-50 (NH₄⁺ form) at pH 6.65 (ref. 17) using authentic samples of 3-MeAde (Fluka) 7-MeGua, thymine (Sigma) and 7-methyladenine (Vega-Fox) as internal standards. The chromatographic identity of ³H-3-MeAde with an authentic sample was independently confirmed using cellulose thin-layer chromatography (Eastman chromatogram)⁸.

above. It has been claimed that endonuclease II of *Escherichia coli*⁸ both excises the alkylated bases 3-MeAde and O⁶-methylguanine (O⁶-MeGua) and incises DNA at

apurinic sites. This enzyme also recognises a number of additional substrates⁹⁻¹¹. To establish the precise mechanism of incision of alkylated DNA we have purified two enzymes from *Micrococcus luteus*, a DNA *N*-glycosidase, which excises 3-MeAde, and an endonuclease for apurinic sites. We report here a reconstruction experiment showing that incision of DNA treated with carcinogenic and mutagenic compound methyl methanesulphonate (MMS) is a two-step mechanism involving the sequential action of these two enzymes.

Endonuclease for apurinic sites was assayed by the release of acid-soluble oligonucleotides¹ from heavily depurinated *E. coli* ³H-DNA. DNA *N*-glycosidase activity is measured by the liberation of ethanol soluble ³H-3-MeAde (Fig. 1) from calf thymus DNA alkylated with ³H-dimethylsulphate. Supertwisted PM2-DNA was used in additional assays to detect endonuclease activity at the level of one nick per molecule. The assay measures the conversion of supertwisted molecules to nicked ones. When using superhelical DNA in the assay of the endonuclease for apurinic sites, a limited number of apurinic sites was introduced by heating at low pH (ref. 19). For DNA *N*-glycosidase few bases were alkylated by MMS²⁰.

The two enzyme activities showed, in our conditions, similar chromatographic properties on DEAE- and P-cellulose columns, but were resolved by a column of DNA-Agarose (Fig. 1). But slight contaminating traces of endonuclease acting at apurinic sites in DNA *N*-glycosidase could be detected up to fraction 12 when using a large excess of DNA *N*-glycosidase (1.1 units) for the PM2-DNA assay. No DNA *N*-glycosidase can be detected in the endonuclease for apurinic sites peak before fraction 7 using 160 units of this enzyme. Neither of the two enzymes were contaminated by nonspecific endonuclease as they did not nick supercoiled PM2-DNA (Table 1). Endonuclease for apurinic sites acts at or near an apurinic site and has no exonuclease associated (J.L. and L. Grossman, in preparation). DNA *N*-glycosidase liberates 3-MeAde from dimethylsulphate-alkylated DNA and very little, if any, of 7-methylguanine (7-MeGua) (less than 5% of the total bases released).

A reconstruction experiment involving the sequential action of the two enzymes described above should be a strong argument for a two-step mechanism for incision of alkylated DNA. Therefore, we devised the following experiment: ³H-labelled PM2-DNA was treated with MMS²⁰ to alkylate about one base per molecule as 3-MeAde²¹, this latter base being a substrate for DNA *N*-glycosidase. Identification of DNA superhelical and nicked forms was achieved by zone sedimentation or by filter assay and average number of nicks per molecule calculated. Untreated PM2-DNA carried an average of 0.06 nicks per molecule (Table 1). Enzymes used had no activity on native DNA as after incubation the average number of nicks (0.10) was not significantly increased (Table 1). This rules out a possible contamination by non-specific endonuclease. Methylation slightly nicks the DNA (Table 1). On incubation of MMS-treated DNA alone or with apurinic endonuclease or with DNA *N*-glycosidase, there was no significant change in the average number of nicks introduced per molecule of DNA, this number being respectively 0.15, 0.17, 0.16 for the three samples studied (Table 1 and Fig. 2 *a, b, c*). In sharp contrast sequential incubation of the two enzymes induced an average of 1.05 breaks per molecule (Fig. 2*d*).

It is the first time that the DNA *N*-glycosidase for alkylated DNA has been obtained devoid of endonucleolytic activity either on native DNA or on DNA-carrying apurinic sites (Fig. 1) and devoid of nicking activity on MMS-treated DNA. Similar specificity has been observed for endonuclease II (ref. 8). The specificity of the DNA *N*-glycosidase for 3-MeAde but not for 7-MeGua correlates

with the *in vivo* studies of Lawley and Warren²², showing that in *E. coli* 3-MeAde is lost much more rapidly than 7-MeGua.

Strauss *et al.*²⁰ showed that crude extracts of *M. luteus* as well as of *Bacillus subtilis* are able to introduce single-strand breaks in alkylated DNA, and that unidentified

Fig. 2 Zone sedimentation profiles of PM2-DNA after incubation without enzyme (*a*) with DNA *N*-glycosidase (*b*), with endonuclease acting at apurinic sites (*c*) and with DNA *N*-glycosidase then endonuclease for apurinic sites (*d*). ³H-labelled PM2-DNA (17 nmol, 3.2×10^7 c.p.m. μmol^{-1}) was alkylated with MMS as described by Strauss *et al.*²⁰ (0.0125 M for 31 min at 37 °C), cooled to 0 °C and dialysed against 5 mM K_2PO_4 buffer (pH 7.5). This substrate is referred as MMS-DNA. The DNA *N*-glycosidase incubation mixture (150 μl) contained 26 pmol of MMS-DNA in K_2PO_4 buffer 0.05 M (pH 7.5) and 0.066 units of DNA *N*-glycosidase (fraction no. 16) incubation is for 20 min at 37 °C. To show the action of apurase the incubation mixture is as above, DNA *N*-glycosidase being replaced by 0.012 units of endonuclease acting for 10 min at 37 °C. Sequential action of the two enzymes is performed by incubating 0.066 units of DNA *N*-glycosidase for 10 min at 37 °C, then adding 0.012 units of endonuclease acting at apurinic sites and incubating the mixture for an extra 10 min. For the action of the enzyme on native PM2-DNA conditions were the same, MMS-DNA being replaced by the same amount of native ³H-labelled PM2-DNA. At the end of the incubation time the samples were cooled to 0 °C and layered on the top of a 4.8-ml sucrose gradient¹⁸ (5–20% in 0.02 M Tris-HCl, 0.002 M EDTA, 0.04 M NaCl (pH 7.08) over a 0.2 ml cushion of saturated CsCl . The samples were then centrifuged (rotor SW 50-1) for 180 min at 4 °C at 43,000 r.p.m. (Spinco L2-75-B). Gradients were collected using an ISCO UA5 fraction collector and counted in Scintigel (Roth). Separation was achieved at low salt concentration which allows the best separation at neutral pH¹⁸. In these conditions, sedimentation coefficients were respectively 29S and 21S for superhelical and nicked forms¹⁸. Centrifugation in alkaline conditions although allowing even better separations¹² cannot be used as they nick DNA at apurinic sites¹⁹. But alkaline denaturation can be performed in the filter assay as time of contact is short (30 s) and without adverse effect (Table 1).

Table 1 Average no. of nicks introduced by various treatments of PM2-DNA

DNA treatment	Average no. of nicks
None (untreated DNA)	0.06
DNA+MMS+dialysis (MMS-DNA)	0.10
MMS-DNA+incubation	0.15
MMS-DNA+DNA <i>N</i> -glycosidase	0.17
MMS-DNA+endonuclease for apurinic sites	0.16
MMS-DNA+DNA <i>N</i> -glycosidase +endonuclease for apurinic sites	1.05
Untreated DNA+DNA <i>N</i> -glycosidase +endonuclease for apurinic sites	0.10

PM2-DNA was alkylated by MMS, dialysed and treated with the various enzymes as duplicates of experiments described in Fig. 2. After incubation, samples were cooled to 0 °C. The DNA was immediately denatured by alkaline treatment, renatured and filtered through nitrate cellulose filter as described previously¹². Single-stranded DNA arising from nicked molecules was retained on the filter, allowing calculation of the amount of supercoiled form in the incubation mixture. The number of breaks (n) per molecule was derived from Poisson's law, $n = -\ln e$, e being the fraction of remaining supercoiled molecules²³.

methylated sites are not substrate for the enzyme(s). These early experiments had not been devised to ascertain if incision of DNA occurred through a single or a two-step mechanism, however. Goldthwait's group showed that a purified although non-homogeneous preparation of *E. coli* endonuclease II, is active on a wide range of substrates⁸⁻¹¹—it nicks depurinated DNA, releases 3-MeAde and O⁶-methylguanine from DNA reacted with *N*-methyl-*N*-nitrosourea⁸, and also nicks unmodified DNA at high concentrations⁹. Verly and Rassart³ isolated an endonuclease in *E. coli* acting at an apurinic site which was obtained homogeneous and shown to be inactive on alkylated DNA. This endonuclease was found to be exonuclease III (ref. 24), a single molecule carrying the two activities assayed independently with different substrates. Kirtikar *et al.*²⁵ isolated from *E. coli* an apurinic acid endonuclease apparently the same as that isolated by Verly and Rassart³ but they consider it not to be exonuclease III. In *E. coli*, another endonuclease acting at apurinic sites and lacking exonuclease activity (endonuclease IV) was obtained homogeneous and shown to be inactive on alkylated DNA⁵.

The model of excision repair of alkylated DNA best supported by our data and the published data on the *M. luteus* system is shown in Fig. 3; part of this scheme was proposed as a hypothetical model by Lindahl⁷. On action of a variety of alkylating agents on DNA (Fig. 3a) at least *N*-7-guanine and *N*-3-adenine became alkylated²¹ (Fig. 3b). 3-MeAde but not 7-MeGua is recognised by the DNA *N*-glycosidase. It cleaves the N₃ C'1 bond between the base and the deoxyribose, yielding a free 3-MeAde and an apurinic site (Fig. 3c). In turn, the apurinic site is recognised by the endonuclease for apurinic site which nicks the DNA (Fig. 3d). It should be recalled that *M. luteus* endonuclease for apurinic site has no exonuclease activity. This could be a disadvantage as DNA ligase could act before the removal of the damaged nucleotide and thus produce an abortive repair. It is possible, however, that DNA binding proteins could prevent this abortive repair (Fig. 3e) as this has been already suggested in the repair of ultraviolet-induced damage¹. The correxonuclease described by Kushner *et al.*²⁶ which is able to excise thymine dimers would be a good candidate to excise apurinic sites yielding a gap (Fig. 3e). The gap thus formed could be filled by a DNA polymerase²⁷ (Fig. 3f) and the continuity of the phosphodiester chain restored by a polynuclease ligase (Fig. 3g). This model has recently received experimental support in the repair

Fig. 3 Model for excision repair of alkylated DNA or uracil-containing DNA. *a*, Unmodified DNA; *b*, alkylation (MMS) giving 3 MeAde (A*) and 7-MeGua (G*); *c*, specific release of free 3-MeAde yielding an apurinic site (DNA *N*-glycosidase); *d*, incision endonuclease for apurinic sites; *e*, a binding protein prevents abortive rejoining; *f*, excision (correxonuclease)—this step could also occur directly after (*d*); *g*, repair replication (DNA polymerase); *h*, resealing (DNA ligase). This model holds true for repair of uracil-containing DNA²⁸ (A* being replaced by U).

of DNA containing uracil where nicking is achieved by sequential action of uracil DNA *N*-glycosidase and endonuclease for apurinic sites²⁸. Endonucleases acting at apurinic sites have been described in calf thymus⁴, HeLa cells²³ and human placenta²⁹. A human binding protein for ultraviolet irradiated DNA³⁰ and a correxonuclease³¹ are described in human placenta. Therefore, our model could also be true for repair in mammalian cells of alkylated DNA, even if so far no mammalian DNA *N*-glycosidase has been described.

In animals treated with alkylating carcinogens (see review 32), certain organs such as the liver seem to be much more resistant to tumourigenesis than the brain or the kidneys. Appearance of tumours is correlated with the persistence of alkylated bases. This suggests that chemical cancerogenesis could be related to defective repair mechanisms such as inefficient cellular DNA *N*-glycosidase.

We thank Drs S. Ljungquist and T. Lindahl for preprints. These studies were supported by INSERM and CNRS and Pierre Philippe Foundation.

Mass spectrometric determination of molecular formulas for membrane-modifying antibiotics

THE peptide antibiotics alamethicin and suzukacillin, together with gramicidin A are of considerable biological interest as they facilitate ion transport across membranes by a mechanism involving pore or channel formation in the membranes^{1–3}. In discussing their mode of action it is, of course, necessary to consider the antibiotics' structures and such discussions have been hampered, especially for alamethicin^{1,4–7}, by incorrect structures originally

proposed for the antibiotics. Thus, the earlier structures proposed for valine-gramicidin A and isoleucine-gramicidin A^{8,9} were revised to **1** and **2** (Fig. 1) following the detection of N-terminal formyl and C-terminal ethanolamine groups¹⁰, and earlier structures^{11,12} proposed for alamethicins I and II have recently been revised to **3** and **4** (ref. 13) following the discovery of N-terminal acetyl and C-terminal phenylalaninol groups^{14,15}. (The partial structure proposed for suzukacillin¹⁶ will probably also be revised in view of the newly reported structure for alamethicin¹³.) Much of the difficulty in assigning structures to these antibiotics has derived from an inability to determine accurate molecular formulas. We have until recently been hampered by the same problem in our studies of the structures of antiamoebein I (**5**) (ref. 17) and emerimicins III and IV (**6** and **7**) (ref. 18), new peptaibophol antibiotics [peptide antibiotics containing several moles of α -aminoisobutyric acid (Aib) and a C-terminal phenylalaninol (Phol) unit] which have been shown to have similar membrane-modifying properties (P. Mueller, personal communication). We have developed, and describe here, a new technique, a modification of field desorption mass spectrometry^{19,20} involving cation exchange, which has allowed us to assign molecular formulas directly to these peptide antibiotics and their derivatives in the 1,500–2,100 molecular weight range.

The cation exchange technique involves adding, systematically, a series of alkali metal salts to solutions of the compounds whose FD mass spectra are being determined, and observing the resulting shifts in the molecular ion region due to cationation. The technique was developed during our extensive studies on the membrane-modifying peptide antibiotic antiamoebein I, whose structure has now been shown²¹ to be **5**. We found it difficult to assign the antibiotic a definitive molecular formula, either from its constituent amino acids or from the highest mass ion in the FD mass spectrum of its triacetate, at m/e 1,818 (peak matched against the m/e 1,790 peak ($C_{35}H_{15}F_{60}N_3O_5P_3$) from hexakis (2,2,3,3,4,4,5,5,6,6,7,7, - dodecafluoro - 1 - heptoxy)cyclotriphosphazene²²), which shifted to m/e 1,860 and 1,902 in the FD mass spectra of the tripropionate and tributryate, respectively.

The masses for the triesters would correspond to a molecular weight of 1,692 for antiamoebein I, which did not agree with any of the possibilities under consideration¹⁷. But, m/e 1,692 would fit for a sodium adduct of one of the considered potential molecular weights, m/e 1,669 ($C_{82}H_{127}N_{17}O_{20}$). To test this hypothesis

Fig. 1 1, Valine-gramicidin A; 2, isoleucine-gramicidin A; 3, alamethicin I; 4, alamethicin II; 5, antiamoebein I; 6, emerimicin III; 7, emerimicin IV. All optically active amino acids and phenylalaninol units shown have the L configuration except those marked D. Aib, α -aminoisobutyric acid; Phol, phenylalaninol; Ac, acetate.

Fig. 2 Field desorption mass spectra of antiameobin I triacetate in the molecular ion region: a, with added lithium chloride (26 mA); b, with added sodium chloride (23 mA); c, with added potassium chloride (21 mA). Peaks due to a small amount of a homologue, antiameobin III, can be observed 14 AMU below the major peaks.

antiameobin triacetate was treated with a saturated methanolic solution of potassium chloride and a 50% saturated solution of lithium chloride. The triacetate's m/e 1,818 peak ($M + Na$; Fig. 2, b) was displaced to m/e 1,834 ($M + K$; Fig. 2, c) and m/e 1,802 ($M + Li$; Fig. 2, a), respectively. In the case of lithium chloride, peaks at higher masses corresponding to ($M + Li + LiCl$) and ($M + Li + 2LiCl$) were also observed (Fig. 2, a), at 1,844 and 1,886. (Addition of rubidium chloride can be even more helpful, since there are two rubidium isotopes (^{85}Rb and ^{87}Rb ; isotopic abundance 2.51:1). In the case of antiameobin I triacetate these gave $M + Rb$ ions at m/e 1,880 and 1,882.)

The intensities of molecular ion peaks were vastly enhanced by this treatment and enormously more durable. (Lithium salts have been added previously, using the FD technique at low resolution with known compounds, to adenosine (molecular weight (MW) 267)²³ and to sucrose (MW 342) and loroglossin (MW 742) (ref. 24). The triacetate's m/e 1,818 peak was matched against the peak at m/e 1,720.9514 ($C_{34}H_{18}F_{56}N_3O_6P_3$) in the FD spectrum of bis (dodecafluorooctoxy) tetrakis (octafluoropentoxo)-cyclotriphosphazene²² at high resolution to give the value 1,818.9596, in good agreement with that calculated for the expected $C_{88}H_{133}N_{17}O_{23}Na$.

The technique works equally well on antiameobin itself. Adding sodium, potassium and lithium chloride solutions to antiameobin I gave strong FD peaks at m/e 1,692 ($M + Na$), 1,708 ($M + K$) and 1,676 ($M + Li$), while addition of sodium chloride solutions to the tripropionate and tributrylate greatly enhanced the peaks at m/e 1,860 and 1,902 ($M + Na$).

The cation exchange technique shows the molecular formula of the membrane-modifying emerimicin IV (6) (ref. 25) to be $C_{77}H_{120}N_{16}O_{19}$ (MW 1,572) by an ($M + Na$) ion at m/e 1,595.8930 and an ($M + K$) ion at m/e 1,611, while its triacetate gave an ($M + Na$) ion at m/e 1,721 and an ($M + K$) ion at m/e 1,737. Emerimicin III (7) (ref. 25), also a membrane-modifier, gave an ($M + Na$) peak at m/e 1,581.8655.

Alamethicin is a mixture of two antibiotics, alamethicins I and II (3 and 4) (ref. 13), each containing a free carboxyl group, and its cation exchange FD mass spectra are more complex. The mixture gave peaks for alamethicin I ($C_{92}H_{150}N_{22}O_{25}$) at m/e 1,984 ($M + Na - H$) and 2,007 ($M + 2Na - H$) and corresponding peaks for alamethicin II ($C_{93}H_{152}N_{22}O_{25}$) at m/e 1,998 and 2,021 in the presence of sodium chloride. Similar peaks were found at m/e 2,000 ($M + K - H$), 2,014 ($M + K - H$), 2,039 ($M + 2K - H$) and 2,053 ($M + 2K - H$) in the presence of potassium chloride, while alamethicin acetate gave peaks at m/e 2,026 ($M + Na - H$), 2,040 ($M + Na - H$), 2,049 ($M + 2Na - H$) and 2,063 ($M + 2Na - H$) in the presence of sodium chloride.

Finally, sodium chloride-treated gramicidin A gave FD peaks at m/e 1,903 ($M + Na$ for valine-gramicidin A, $C_{99}H_{140}N_{20}O_{17}$, 1)

and at 1,917 (the same peak for isoleucine-gramicidin A, $C_{100}H_{142}N_{20}O_{17}$, 2), while treatment with potassium chloride shifted these peaks to m/e 1,919 and 1,933 ($M + K$ for valine- and isoleucine-gramicidins A, respectively).

We are now extending our studies to establish the scope of the cation exchange procedure in assigning molecular weights to additional antibiotics and to compounds of other structural classes of high molecular weight or low volatility.

New rapid gel sequencing method for RNA

METHODS for sequencing nucleic acids have improved significantly in the last few years due to the development of rapid 'read-off' gel methods. The first method to be developed was the 'plus and minus' copying method for DNA¹ and an analogous copying

method for RNA now exists². A different and more direct method for sequencing DNA has been developed³, but no direct method is available for RNA. We have developed such a method and here we describe its use in establishing the sequence of tyrosine tRNA of *Bacillus stearothermophilus*. This sequence is especially interesting as the tyrosine tRNA and its specific synthetase in *B. stearothermophilus* offer an attractive experimental system for studying the specific interaction of tRNA and synthetases, which is now possible because of progress in studying the three-dimensional structure of the protein by X-ray crystallography⁴.

Classical radioactive sequencing methods⁵ applied to uniformly ³²P-labelled tRNA were used initially to sequence the products of complete T₁ or pancreatic RNase digestion (Table 1). Only brief reference to this work is made here as an extensive report will be published elsewhere (R.S. B. in preparation).

Overlapping of the products in Table 1 was achieved by the development of the new sequencing procedure, which is similar in principle to that used by Maxam and Gilbert for DNA³ except that enzymatic rather than chemical methods were used to degrade the RNA and to define the base-specific point of cleavage. Thus the design of the experiment was to label the RNA at its 5' terminus with ³²P-phosphate and partially digest separate aliquots with either T₁ RNase (G-specific), U₂ RNase (A-specific in partial conditions), pancreatic RNase (C + U-specific), or RNase I from *Physarum polycephalum*⁶. Phy I RNase is less well known than the other enzymes and it emerged^{7,13} that its base specificity was such that it could cleave at all residues except C. Hence we refer to its activity as minus C (–C). The digests were then fractionated in adjacent slots of a 20% denaturing acrylamide gel. The base specificity of these four enzymes should provide enough information to allow the sequence to be 'read-off' from the resultant autoradiograph.

Figure 1 shows the purification of ³²P-5' end-labelled tRNA using γ-³²P-ATP and T₄ polynucleotide kinase by acrylamide gel electrophoresis. In addition to intact tRNA^{Tyr} (band 1), many degradation products were present in lower yield. Bands 1 and 2 were selected for sequence analysis. Figure 2 shows the sequencing method applied to the 5' end-labelled fragments of tRNA^{Tyr} (Fig. 1, band 2) which was identified as deriving from residues 38–85 in the finally deduced sequence (Fig. 4). The enzymatic degradations are identified as G, A, C + U and –C (performed in duplicate and applied at separate times so as to maximise resolution of both fast and slow moving bands). A fifth slot (hot formamide degradation) giving a ladder (L) of every possible intermediate was also included. Hot formamide degradation (P. H. Hamlyn, personal communication) is preferable to partial alkaline hydrolysis for this purpose as it gives oligonucleotides with the same 2', 3'-cyclic phosphate end group as in the enzymatic degradations. Partial alkaline hydrolysis with strong base, on the other hand, gave both

2',3'-cyclic phosphate and a mixture of 2' and 3' phosphate end groups which separated from one another and confused the ladder in the size range of 1–10 on the acrylamide gels.

The sequence may be read from residues 38–83 with the single ambiguity X63, due to the presence of a minor base (see below). G residues are identified without difficulty from the highly specific G slot. 'A' residues are usually present in the A slot as strong bands, although also present are some G and pyrimidine bands. The latter are clearly distinguishable by their low yield and by the presence in the G or C + U slots. The pyrimidine residues are more difficult to identify than the purines, although the C + U and –C slots can be 'read' together to give the correct sequence. C residues are identified by their presence (usually as strong bands) in the C + U slot and by their absence (or low yield) in the –C slot. U residues are identified by the presence of a band in both C + U and –C slots. Usually U residues are stronger in the –C slot than the C + U slot. In this particular experiment the presence of a band, C65, in the –C slot (as well as in the G and A slots) is misleading as it was also present in a control line (not shown) and derived by nonspecific degradation of the RNA during its purification and storage. The sequence overlapped and was in complete agreement with the data in Table 1, apart from the identification of modified bases and the last two residues at the 3'-end. X63 was clearly the T residue of the oligonucleotide t9 (Table 1) and was presumably resistant to digestions in the C + U and –C slots in the partial conditions used. Both Ψ residues (residues 40 and 64) behaved like U residues, and the hyper-modified ms²i⁶A (residue 38) was only a weak band in the A slot.

Figure 3 shows the sequence analysis of intact tyrosine tRNA (Fig. 1, band 1). In this case the sequencing was more difficult than with the fragment as some degradation products were absent or in low yield. This presumably reflected the inability of the enzymes to attack helical regions in the structure. Preliminary experiments with brewers yeast tRNA^{Phe} had shown that a more even intensity of the bands was present in the G and C + U line if 70% dimethyl sulphoxide (DMSO)⁹ at 37 °C was used to denature the tRNA. Unfortunately DMSO could not be used for studies on tRNA^{Tyr} because of a 'band doubling' phenomenon on the gels, which seemed to be caused by oxidation of the s⁴U residue not present in tRNA^{Phe}. Further studies showed that 70% formamide could be used as an alternative but was not quite as effective as the DMSO. Thus Fig. 3 includes several variations in the conditions of enzymatic degradation: 'C + U, condition 3' was a reaction in formamide and was a slight improvement over the other two aqueous digestions; '–C, conditions 1 and 2' and 'C + U, conditions 1 and 2' were variations in the amount of enzyme or time of digestion in a further attempt to obtain as even a spectrum of products as possible. The sequence can, nevertheless, be read from Fig. 3 from residues 2 to 34 with only four ambiguities—

Table 1 End products of T₁ and pancreatic RNase digestions of tRNA^{Tyr}

T ₁ end products	Pancreatic end products

	p17 pG – G – A – G – G – G – G – s ⁴ U

Uniformly ³²P-labelled tyrosine tRNA (*B. stearothermophilus*, NCIB 8924) was purified by acrylamide gel electrophoresis (R.S.B., in preparation) and fingerprints of T₁ and pancreatic RNase digestions were prepared using two-dimensional electrophoresis (cellulose acetate at pH 3.5 followed by DEAE-cellulose ionophoresis using 7% formic acid). Oligonucleotides were sequenced by standard methods⁵. Minor bases were identified by their chromatographic properties on thin layers⁸.

partially denaturing conditions used than were T_1 or pancreatic RNases. Nevertheless tRNA is a particularly difficult example with its 'tight' structure, and many RNA molecules to which the method is applicable would have far less secondary structure.

The technique described here compares favourably in its rapidity and sensitivity (less than 0.1 μ Ci RNA per gel is needed) with the plus and minus method for RNA²; furthermore it is independent of any requirement for oligonucleotide primers². Although we do not claim that the method is 100% accurate, it is promising enough to apply to other RNA molecules. There is no doubt that it is the easiest way of establishing a tentative new sequence, which could be confirmed by more classical methods if necessary. The method in principle is also applicable to 3' terminally-labelled RNA. Preliminary results have shown that ³²P 3'-labelled tRNA^{Phc} (labelled using α -³²P-ATP and the enzyme tRNA nucleotidyl transferase¹⁴) is suitable; ³H-borohydride labelled RNA¹² is more generally applicable and we expect this also to be a suitable substrate. The flexibility of using either 5' or 3'

Fig. 3 Sequence analysis of intact tRNA. Letter symbols are as described in Fig. 2. Three separate experiments with pancreatic RNase (C+U, (1) 0.3 ng, (2) 0.5 ng enzyme as in Fig. 2, (3) 0.5 ng enzyme in 70% aqueous buffered formamide, 37 °C, 30 min); two with *Phy* I RNase (1 μ l enzyme solution, for 5 min and for 20 min) were performed.

Fig. 4 Sequence of tRNA^{Tyr} of *B. stearothermophilus*.

labelled material should allow the sequencing method to be extended to larger RNA molecules, such as 5S RNA and larger, although there is still a limitation of about 150–200 residues² in the resolution so far obtained in sequencing gels. Finally the method has the potential (not explored here) of probing for conformation of RNA in solution in physiological conditions. Further, the band pattern characteristic of the conformation of the tRNA is likely to be altered when the molecule is complexed with its specific amino acid synthetase. This should give important insight into the specificity of recognition in this tRNA-protein interaction.

While this work was in progress Gupta and Randerath¹² reported a related method using thin-layer chromatography on PEI-cellulose to 'read off' sequences of up to 20 residues in length. As *Phy* I RNase was not used, however, the method was more cumbersome and relied on two-dimensional methods to distinguish the pyrimidine residues. After submission of this report a gel mapping procedure for guanine and adenine residues was reported¹⁵, but a complete sequence could not be established as no method was presented for distinguishing pyrimidine residues.

We thank Professor W. Fiers for suggesting the use of *Phy* I RNase, and Dr J.-P. Bargetzi for providing the enzyme. A.S. is a visiting UNESCO Scholar from the Institute of Biophysics, Hungarian Academy of Sciences, Szeged.

reviews

State of medicine in the US

W. W. Holland

Doing Better and Feeling Worse. Edited by J. H. Knowles. Pp. 287. (W. W. Norton: New York, 1977.) Hardback \$9.95; paperback \$3.95.

This interesting collection of essays written by leading personalities in the fields of medicine, politics, economics and the social sciences presents an analysis of opinion of the state of medicine in the United States. As such, it rarely refers to work in other countries but in discussion of such aspects as health insurance, the place of private medicine and development of training for primary care it will be of interest to all those concerned with development of health policies in a number of countries.

The book was written following an invitation by Nelson Rockefeller in his capacity as Vice-President and Chairman of the Commission on Critical Choices for Americans to John Knowles, President of the Rockefeller Foundation, to organise a group to study the problems of health care. A number of the contributions were first submitted as drafts prepared for study by the Commission.

The book covers a wide range from the apparent increase in "medicalisation" of American society, ethical factors such as the right to die—in this particular chapter, "Therapeutic Choice and Moral Doubt in a Technological Age", a detailed description of the Karen Quinlan situation is given—to the place of science and technology, the responsibility of the individual, the challenge of primary care, a look at political aspects of health policy (including relationships between government), the consumers and the providers, and the role of the physician. The book also includes chapters covering financing, research, the needs of children and of mental health.

The major theme of several of these essays does not vary much from that preponderated by Thomas McKeown in his recent text *The Role of Medicine* or that of Ivan Illich in *Medical Nemesis: The Expropriation of Health*. Aaron Wildavsky, author of the chapter entitled "Doing Better and Feeling Worse: The Political Pathology of Health Policy", states that the great equation Medical Care equals Health is wrong. "More available medical care

does not equal better health. The best estimates are that the medical system (doctors, drugs, hospitals) affects about 10% of the usual indices for measuring health: whether you live at all (infant mortality), how well you live (days lost due to sickness), how long you live (adult mortality)". He continues by saying that since the other 90% are affected by life-style and social and environmental conditions, "most of the bad things that happen to people are at present beyond the reach of medicine".

Walsh McDermott, in his chapter entitled "Evaluating the Physician and His Technology", takes this point a bit further by saying that it is wrong to say that the personal encounter physician has little influence on health but he lacks influence on the indicators of community health largely devised in the eighteenth, nineteenth and twentieth centuries for a different purpose. He continues, however, by saying that we in fact lack measures of the physician's ability to "modulate the deranged physiology of ultimately fatal chronic disease". McDermott's conclusion on the note that doctors play, coincides with that of several other authors.

Another valuable point made by several authors is that a half-way stage has been reached in the development

of medicine. Major advances have been made but the gains in the past have been fairly minimal compared with what might be expected in future. The book contains the underlying messages of the need to change life-style and the false expectations that populations have of medicine. Further points particularly mentioned by David Callahan in his chapter, "Health and Society: Some Ethical Imperatives", are "the breakdown of the ethical distinction between need and desire in our culture" and also "the continuing utopian lure of technology, a lure whose net effect is to thwart any attempt to place limits on medical aspirations".

This book, despite its impressive variety of subject matter, does not really state much that is new. The particular question, however, that comes to mind is can such publications as this and that of McKeown, Cochrane and Illich have any influence on consumers, providers, or governments; and if they can, will this result in greater rationalisation of requirements for health care? □

W. W. Holland is Professor in the Department of Community Medicine at St Thomas's Hospital Medical School, London, UK.

Control of cellular differentiation

The Differentiation of Cells. By N. Maclean. Pp. iii+216. (Edward Arnold: London, 1977.) Hardback £12; paperback £5.95.

THIS volume, the first of a series entitled *Genetics-Principles and Perspectives*, covers one of the central problems in developmental biology—the control of cell differentiation. There are now several recent texts which cover aspects of the control of gene expression in developing systems. The present volume presents a wide ranging view of current problems.

The first chapter discusses multicellularity in relation to the evolutionary significance of differentiation. Thereafter, the chapters cover differential gene expression, control mechanisms in gene expression, the cytoplasm in differentiation, the role of

hormones, episomes and viruses, the cell surface, and cancer and differentiation. The book ends with the author's views of the important unanswered questions in this field and the experimental systems that hold special promise for their elucidation.

The wide range of subject matter reflects the enormous range of controls which may operate in the orderly progression of cells to their terminally differentiated states, and the maintenance of these states once achieved. A major aspect of the control of cell differentiation is the regulation of gene activity. In introducing the problem of differentiation Dr Maclean emphasises most strongly that "differential gene activity may be a result of differentiation, rather than its causal mechanism". I found this introduction confusing because the terminology is not defined. It is unfortunate that the

book does not have a glossary, since, as the author points out in the case of heterochromatin, the implication of particular terms can change with time.

The subject material is laid out in a readily accessible manner and profusely illustrated with diagrams. The significance of some of the illustrations to the text (for example, the fibre autoradiographs p. 94) is, however, not clearly stated, and in the section on histones only the old nomenclatures are used. At various places the clarity of information has been enhanced by tabulation, though this format in some cases (for example, observations explicable by the master-slave hypothesis) has limited discussion of points which

may have alternative explanations.

A wide range of experimental systems and approaches have been used throughout the text. Perhaps as a consequence of this there are places where advanced students will need greater detail. The questioning style in which the text is presented should motivate the undergraduates and graduates for whom it was written to follow up the references to specialist reviews, and stimulate them to deeper consideration of the complex but intriguing problems of cell differentiation.

Lunar science

The Moon Book: Exploring the Mysteries of the Lunar World. By Bevan M. French. Pp. 287. (Penguin: New York and Harmondsworth, UK, 1977.) \$4.95; £1.95.

THIS is a book for the layman, as might be guessed from the name of the publisher rather than from the presumptuous title. A reader who has some general acquaintance with the Earth sciences, however, will find considerably greater profit in it than the 'intelligent layman' who starts from a state of near-total ignorance.

May natural inclination was to turn first to chapter 10, entitled, "The Lunar Interior: Mapping with Echoes". It contains a disappointing discussion of deductions made from geophysical evidence about the lunar interior. The seismic evidence which has been included seems to be a simplified rehash of the appropriate section of Ross Taylor's 1975 book, referenced in the bibliography.

There are some elementary errors, such as the statement that the inner core of the Earth is under a pressure of nearly a million atmospheres—in fact, it is over three million atmospheres—and a confusion between kilometres and miles in the figure showing cross-sections of the Earth and Moon. But the worst error I found was in the discussion about the Moon's ancient magnetic field, and whether it could have been provided by a molten iron core which has since frozen. French suggests this is unlikely because, "A large body like the Moon loses heat only by the slow conduction of heat through its interior." Ignorance of modern ideas about convection in planets, with the consequent ability for planetary interiors to lose heat at rates several orders of magnitude above conduction

rates, is appalling in a work of this kind.

The author also seems to confuse the ideas of a lunar asthenosphere and a possibly molten lunar core. Deep moonquakes occur in a zone between 600 and 1,000 km from the surface, whereas the lunar radius is 1,738 km. Seismic signals penetrating below this depth have rarely been observed. This suggests attenuation in a region where the pressure is similar to that in the Earth's low velocity zone, at a depth of around 100 km; so, by analogy it may be inferred that the lunar mantle at 1,000 km depth must be in a similar state to the material in the Earth's low velocity zone, possibly including some partial melt, in order to cause the seismic attenuation. Best estimates for the Moon's moment of inertia factor, plausibility arguments about planetary heat transfer and another tenuous piece of seismic evidence, not available to Ross Taylor, combine to suggest that if the Moon does have a metallic iron core, it is probably solid and not more than 500 km in radius.

In the rest of the book the author is on more familiar ground. He gives a very readable account of the pre-Apollo ideas of the Moon's origin and history, the Apollo missions themselves, and the knowledge gained from studies of the returned samples of rock and lunar soil. A set of thirty-six black and white photographs illustrate the story well. The final chapter rounds off the book nicely with a discussion of future developments.

I can recommend this book for general reading provided that the more technical reader bears in mind the author's qualifications as a geologist and geochemist. It would benefit substantially from a rewriting of chapter 10, possibly by a co-author.

Plasma low density lipoproteins

Low Density Lipoproteins. Edited by C. E. Day and R. S. Levy. Pp. xx+445. (Plenum: New York and London, 1977). \$47.40.

THIS book, written by several authors, provides up-to-date information on the structure and metabolism of plasma low-density lipoproteins (LDL), together with an examination of their comparative biology and their relationship to disorders of lipid metabolism and atherosclerosis. The material is grouped in five sections, comprising a total of 15 chapters which provide good critical coverage of the various topics.

The reader is likely to appreciate the efforts of the editors, authors, and publisher to condense a large body of information into a single, well-organised volume. For example, the section devoted to the discussion of "Aberrations of Metabolism" presents a rather detailed description of the pathogenesis and treatment of a few selected genetic disorders, identified as hyper- β and hyperpre- β lipoproteinaemia, type III hyperlipoproteinaemia (also known as "broad β disease" or dysbetalipoproteinaemia), and abetalipoproteinaemia, together with an analysis of the variants of LDL with particular reference to the Lp(a) antigen.

The section on "Comparative Biology", which gives a good overview on the LDL of mammals and non-mammalian vertebrates, is of particular interest. Concerning atherosclerosis, a useful discussion is presented on the interactions *in vitro* of LDL with either small polyanions (heparin and dextran sulphate) or macromolecules (collagen and elastin); these interactions are believed to play a role in the deposition of LDL in the arterial wall and in atherogenesis.

Perhaps the least rewarding section for both authors and readers may prove to be that dealing with LDL structure, since much of the current information, particularly on the LDL protein, is rather uncertain and is still the subject of an active research pursuit.

Overall, this is a good book, especially for investigators in the lipoprotein field who are likely to find both the condensed information and the more than 1,500 citations very valuable for their work.

Angelo M. Scanu

Applying physics to chemistry

Modern Physics in Chemistry. Vol. 1. Edited by E. Fluck and V. I. Goldanskii. Pp. xiii+406. (Academic: New York, San Francisco and London, 1977.) £18.50; \$36.10.

THIS is a collection of papers intended to describe the basic principles of some of the experiments of modern physics which have in the past decade been applied with such signal success to the problems of chemistry. It is not, as could easily have happened, primarily a collection of the various new spectroscopies, although inevitably resonance methods feature strongly. Chapters on positronium and mesic chemistry vary the diet.

This is not a unified, critical or comparative text which would serve, say, for the education of physical chemists in newer methods. This is a disappointment for there is always room for well written interdisciplinary teaching books of this kind. It may, however, be interesting for the researcher to have under one cover such a collection of reviews which, though they are now rather dated (the manuscripts were collected in 1973), provide a useful insight into the Russian literature in some of the areas.

Two chapters on X-ray spectroscopy divide into valence shell and band structure and core level shifts, respectively. They are, however, really too brief to provide a useful

survey of this rather slowly but long developing field. Electron paramagnetic and nuclear quadrupole resonance methods have much fuller coverage. Nuclear magnetic resonance is not featured; it is not "modern" any longer, except in the form of chemically induced dynamic nuclear polarisation. Mossbauer spectroscopy is brought up-to-date with Mossbauer double resonance experiments.

Although a different viewpoint on these newer techniques is to be welcomed, it is rather difficult to see much benefit being derived from this first volume by anyone outside the ranks of the historians of science. Unfortunately, in translation, clarity has somehow escaped and even post-graduate students will find quite a lot of up-hill work, sometimes intelligent guesses being necessary to perceive exactly what the authors mean. There is little evidence of editorial effort to attain a unity of style or to secure an error-free translation (Gammett constant?) although stilted or archaic usage can, as the late Gerard Hofnung showed, have charm. More serious slips are to be found, including a blatantly erroneous diagram of nodal surfaces for the benzene π orbitals. It seems as if the chemists' voice has been too weak throughout. It is difficult to see who would be recommended to pay £18.50 for this volume.

D. W. Turner

D. W. Turner is Lecturer in Physical Chemistry at the University of Oxford, UK.

Gas chromatography methodology

Modern Practice of Gas Chromatography. Edited by R. L. Grob. Pp. (Wiley-Interscience: New York and London, 1977.) £16; \$28.

THERE are now so many good books on the theory and practice of gas chromatography that a newcomer to the ranks must be of high quality indeed to stand any chance of acceptance. The book under review has the now almost universal style of a multiplicity of authors, each of whom holds responsibility for his own chapter and the editor for the resultant patchwork. The subjects covered separately are: Introduction (history and nomenclature); Theory and Basics; Columns and Column Selection; Qualitative and Quantitative Analysis; Detectors; Instrumentation; Trace Analysis; Selection of Analytical data (data handling); Analysis of Foods; Clinical Applications; Physico-Chemical Measurements;

and Drug Analysis.

The sections are very variable. The best is by Touchstone and Dobbins on "Clinical Applications", where the descriptions are clear, concise and accurate and the authors have actually read papers appearing before 1968. One of the less good sections is that dealing with instrumentation where the illustrations are frequently commercial black boxes that convey no information at all (except advertising). The editor also needs to note that the same illustration is used on page 355 as on page 173 in a different chapter.

All-in-all, the book is rather like the curates egg (good in parts); and with a well understood and practised technique like gas chromatography, this is not good enough. This is a pity, since a lot of hard work has gone into the chapters; a clearer intent as to what needs to be put across in each section would have produced a shorter and better book.

A. T. James works in the Colworth Laboratory of Unilever Ltd, Sharnbrook, UK.

Organosulphur chemistry

Organic Chemistry of Sulfur. Edited by S. Oae. Pp. ix+713. (Plenum: New York and London, 1977.) \$48.

THE importance of organosulphur chemistry, as demonstrated by its rapid growth over the past decade or so, has meant that a book covering this area in breadth and depth is somewhat overdue. Twelve chapters on various aspects are contained in the book and these and their contents are arranged in a logical sequence. Each of the chapters is written by one or more leading authorities; and it is a compliment to the contributors and to the editor that, although individual styles are apparent, continuity is maintained.

In the first chapter, the basic theoretical aspects of sulphur bonding are described. This is followed by a discussion of elemental sulphur and its reactions, which provides a necessary introduction to the vulcanisation of rubber covered in the third chapter. The remaining chapters deal with the physical and chemical properties of specific sulphur compounds—thiols, thiones, sulphides (mono-, di-, and poly-), sulfoxides and sulphilmines, sulphonium salts, sulphones and sulfoximines, sulphinic acids and esters, and sulphonate and sulphate esters. Some detail is also given to sulphur biochemistry within various chapters.

On the credit side, the book contains many excellent qualities with the diagrams, tables and general layout being attractive and comprehensive. The mechanistic approach used is also a highly commendable feature.

On the debit side, however, it is surprising that the industrially important sulphonic acids are not discussed in some detail. Furthermore, over 2,300 references are quoted, but no references later than 1973 are included and very few 1972 or 1973 references are given. In fact, for the majority of the chapters, the literature is covered adequately only to the end of 1971 and for one chapter only to the end of 1970. This overlong delay between completion of the manuscript and publication must detract in some degree from the overall usefulness of the book.

In spite of these drawbacks, and the presence of a considerable number of trivial and typographical errors, the book is worthy of a place in chemistry libraries and on the bookshelves of the more affluent workers in the field.

A. E. Tipping

A. E. Tipping is Reader in Organic Chemistry at the University of Manchester Institute of Science and Technology, Manchester, UK.

Karst landforms

Morphogenetics of Karst Regions. By L. Jakucs. Pp. 284. (Adam Hilger: Bristol, UK, 1977.) £17.

THIS book is a revised and enlarged version of an original text by the Hun-

garian geographer, Professor Jakucs. The generally good translation is by B. Balkay. In recent years there has been a number of books in different European languages on the landforms of karst (massive limestone) regions, but this book is the first to focus primarily on the processes and origins of karst landforms. It therefore not only fills a gap in our literature on karst but is

also a highly perceptive contribution to the subject.

After discussing the concepts of karst and of karst corrosion Jakucs treats the subject under the main factors which control karstification. These he lists as petrovariance; epirogenic movement (that is, structural variance); climatic variance; erosional and geomorphological variance; and anthropovariance. Each of these controls is discussed in length, and this forms the main theme of the book. The author aims to show that all variations of karst can be discussed in the light of the variants proposed.

The treatment of each section is comprehensive and the discussion covers some ground familiar to karst geomorphologists. But the text is illuminated by Jakucs' own illustrations and careful experiments, which form the main scientific contribution of the book. There are certain sections which are therefore new and also controversial to the English karst morphologist. Four aspects are of particular interest. The first is that dealing with the effects of limestone crystallinity and lithostructure on karst corrosion. The second discusses the effects of soil microclimates on the development of karst depressions. Thirdly, the author has some interesting observations to make on the role of geomorphological situation and erosional variations on the origin of karst landforms; he usefully differentiates between authigenic and allogenic karst evolution. And fourthly there is an extended discussion on the effects of man on karst evolution; the results of deforestation, of spring development and of dam building are among the topics included. The author is perhaps least at home when dealing with the effects of climatic factors on the development of karst; even here however, he has some shrewd comments to make, though he has had to rely mainly on the published literature.

The book is well illustrated with clear diagrams and photographs. The bibliography is especially good on Central and Eastern European works, but shows a lack of knowledge of the more recent Western European and American work (that is, since 1970).

The Hungarian school of karst morphology has long been distinguished for its contributions to all aspects of karst, both surface and underground. Professor Jakucs' book illustrates the depth and grasp of Hungarian work in this field, and his succinct work should be carefully read by all English workers in karst geomorphology.

M. M. Sweeting

M. M. Sweeting is Lecturer in Geography at the University of Oxford, UK.

Illustrations taken from *Food: The Gift of Osiris* by W. J. Darby, P. Ghalioungui and L. Grivetti (Academic: London, New York and San Francisco, 1977; two volumes £12.50/\$27 and £12.50/\$25). These two volumes detail exactly what is known about ancient Egyptian food and eating habits. The book considers medical as well as nutritional uses, and provides a wealth of archeological and anecdotal information. *Top*, Sacred ibis drawn by scientists accompanying Bonaparte in 1799. The bird was associated with the god Thot, master of knowledge and secret science. Strict measures were taken to protect the bird in ancient Egypt, but it has since become extinct in that region. *Bottom*, Hand fish net (tomb of Ka-Gem-Ni at Saqqara, Old Kingdom, sixth dynasty, reign of King Teti, about 2390 BC). Open mouth V nets were used to collect fish which had been channelled into a fenced barricade, and this type of net is still in use today.
